

# Understanding the Doctrine of Patentable Subject Matter\*

Jing-Yuan Chiou<sup>†</sup>

April 2010  
(Preliminary and incomplete.)

## Abstract

The doctrine of patentable subject matter precludes basic inventions such as abstract ideas and laws of nature from patent protection. It is at odds with current economic thinking of the patent system, which stresses the necessity of rewarding pioneering inventors in the cumulative innovation process. In a two-stage innovation model where the first stage invention (basic invention) has no stand-alone value, but the pioneer can also participate in the second stage, I show that, to promote the overall success, rejecting patents on the basic invention is more likely to be optimal when the pioneer has higher capacity, but the follower has lower capacity to engage in the second stage innovation.

# 1 Introduction

In the past two decades, we've witnessed a paradigm shift in the economic understanding of the patent system. Economists have departed from the discrete innovation environment (Nordhaus, 1969, Gilbert and Shapiro, 1990, Klemperer, 1990), and appreciate that R&D is a continual process where each discovery opens a door for future research and each invention builds on knowledge previously acquired in the same or adjacent fields (Green and Scotchmer, 1995, Scotchmer, 1996, O'Donoghue, 1998, Denicolò, 2000, Bessen and Maskin, 2009). Reflecting its sequential nature, the literature of cumulative innovation emphasizes the needs to properly protect early stage inventions, and focuses on how to adjust patent rights to latter inventions in order to balance R&D incentives at different stages of the innovation process.<sup>1</sup>

Patent law does not always enthusiastically embrace the strong support of basic inventions, however. The Supreme Court of the United States has long held that “[h]e who discovers a hitherto unknown phenomenon of nature has no claim to a monopoly of it which the law recognizes. If there is to be invention from such a discovery, it must come from the application of the law of nature to a new and useful end.”<sup>2</sup> Established in case law, the doctrine of patentable subject matter (henceforth, the DPSM) precludes the following from the realm of patent protection:<sup>3</sup>

principles, laws of nature, mental processes, intellectual concepts, ideas, natural phenomena, mathematical formulae, methods of calculation, fundamental truths, original causes, motives, [and] the Pythagorean theorem. . . .

*Applications* of abstract ideas and principles, instead, may be patented, provided that they also satisfy other requirements such as novelty, non-obviousness, and usefulness.

Understanding laws of nature or discovering new ideas very often entail substantial knowledge spillover as they provide new and fertile grounds for future research. These activities arguably require no less time and effort than designing applications around these concepts. The DPSM seems at odds with the insights from cumulative

---

<sup>1</sup>See Scotchmer (2004) for a literature review. Bessen and Maskin (2009), however, argues that the patent system should be abolished in the cumulative innovation environment.

<sup>3</sup>*In re Bergy*, 596 F.2d 952, 201 U.S.P.Q. (BNA) 352 (C.C.P.A. 1979). See also Merges (1997). The European Patent Convention excludes the following from patentable inventions: (a) discoveries, scientific theories and mathematical methods; (b) aesthetic creations; (c) schemes, rules and methods for performing mental acts, playing games or doing business, and programs for computers; and (d) presentations of information (<http://www.epo.org/patents/law/legal-texts/html/epc/1973/e/ar52.html>).

innovation theory (Eisenberg, 2000). For sure, one may find other justifications for the DPSM, such as the difficulty to enforce patent rights based on abstract ideas or mental process, or the somewhat ambiguous difference between “discovery” and “invention.”<sup>4</sup> Since the patent system is designed to “promote the Progress of Science and useful Arts,”<sup>5</sup> in this paper I address the discrepancy between economic theory and patent law practice from the point of view of innovation incentives. I ask: When is it optimal to enable the DPSM and deny patent protection to basic inventions in order to enhance the technological progress?

Consider a two-stage innovation process, where the completion of the first stage is a pre-requisite to start the second stage (Green and Scotchmer, 1995). At the first stage, a pioneering inventor aims to create, or discover, an abstract idea. The abstract idea has no stand-alone value; further efforts are required to find practical applications of the idea. At the second stage, the pioneer and a following inventor sequentially search for the (same) application. I let the pioneer search first, and the follower search only when the pioneer does not come up with the application. To focus on the DPSM, I assume that the application is always patentable, and will always infringe on the abstract idea should the latter become patentable. The only policy instrument is the degree of patent protection conferred to the abstract idea.

To raise the overall innovation rate, i.e., the probability that the application will be discovered,<sup>6</sup> I find that the DPSM is more likely to be optimal when, at the *second* stage, the pioneer has better search capacity, while the follower is less likely to make the discovery, i.e., when his search cost is more likely to be large and so the probability to incur the cost and find the application is small. Consistent with the literature, granting a patent on the abstract idea boosts the pioneer’s first stage innovation incentives and alters the follower’s search decision. This policy also reduces the pioneer’s search incentives at the second stage: if she does not invent the application, she can still use the patent rights on the abstract idea to get a share of the follower’s expected surplus. Therefore, besides considering incentives of different generations of inven-

---

<sup>4</sup>In *Gottschalk vs. Benson*, 409 U.S. 63 (1972), the Supreme Court states that: “It is conceded that one may not patent an idea... The mathematical formula involved here has no substantial practical application except in connection with a digital computer, which means that if the judgment below is affirmed, the patent would wholly preempt the mathematical formula and in practical effect would be a patent on the algorithm itself.” This argument could be analyzed as one with patent scope, i.e., whether to allow a patent with a very broad scope such that it covers all inventions using the algorithm.

<sup>5</sup>U.S. Constitution, Art I, sect. 8, cl. 8.

<sup>6</sup>In Section 4, I show that the DPSM is not optimal when using the two inventors’ joint surplus as the policy objective.

tors, there is a need to balance the *same* inventor's incentives at different innovation stages. This concern dominates as the pioneer's *second stage* capacity improves, but the follower's capacity deteriorates. When the follower has a rather small probability to find the application (even without the threat from the patent on the abstract idea), there is not much surplus to transfer from the follower to the pioneer. Patenting the abstract idea has limited benefit on the first stage innovation, and the second stage discovery probability is dominated by the pioneer's performance. When the pioneer can find the application with a significant probability, *provided that* she is willing to do so, the negative effect of such an "early reward" on her search decision can be non-negligible. The DPSM then is justified as a way to preserve the pioneer's continuing efforts in research.

This result implies that abstract ideas or basic inventions should not be patentable if great first-mover advantage can be derived from engaging in fundamental research, while a new comer, lacking the experience at the earlier stage, faces a substantial obstacle to join the rank. But as the innovation process becomes more "democratic," i.e., as knowledge and research capacity disseminate and are no longer concentrated on a few "early stars," then it would be optimal to start patenting abstract ideas or early inventions. Alternatively, the pioneering inventor's and following inventor's capacity may be different in kind. The pioneer may be good at perfecting the basic invention or better understanding its fundamental properties, and follower may have advantage in identifying particular use of the basic invention and adapting it to specific contexts. The relative importance of these two capacities then depends on the phase of technological progress. To the extent that further understanding the basic scientific principles has priority in primitive technology fields, basic inventions or abstract ideas should become patentable only in mature fields.

An interesting feature of this model is that strengthening the patent protection to the basic invention does not necessarily hamper the second stage innovation. Although it weakens the pioneer's search incentives, there are two opposite effects on the follower's search incentives. A negative effect is the direct concern to share the fruits with the pioneer. But when the application may exist only with a probability, a lower search intensity from the pioneer will boost the the follower's search incentives. The positive effect comes from an information channel in the sequential search structure, and the assumption that an inventor's search cost is private information. Since the follower searches only if the pioneer hasn't found the application yet, the latter's

failure delivers a bad news about the existence of the application, and the more so the more intensively the pioneer searches. Along the equilibrium path, the pioneer's lower search effort after obtaining a patent on the basic invention will raise the following inventor's (updated) belief when it is his turn to search. The direct negative effect is mitigated by the boost in belief. This positive effect may be strong enough to raise the overall second-stage performance after the patenting of abstract ideas. When this is true, patenting the basic invention is beneficial to both stages of innovation. A necessary condition for the DPSM to be optimal, then, is that it has to enhance the second-stage innovation probability.

This finding provides another interpretation of the shrinking of the DPSM since the 1980s. Through a series of court decisions, particularly in computer software and biotechnology, the scope of patentable subject matters has drastically increased in the U.S. (Kuhn, 2007). Despite rapid expansions, some commentators have warned that rewarding patents to abstract ideas would do more harm than good to the long-term development in these fields. And it is an often raised hypothesis that these industries could have done better had these basic patents been denied.<sup>7</sup> My result nevertheless suggests a less gloomy role of basic patents. It also implies that these patents may promote the disintegration of the innovation market. The pioneer has lower search incentives after obtaining a patent on the abstract idea. When the belief-based positive effect substantially offsets the negative effect of rent transfer, the conditional probability that the application is discovered by the follower increases, and so the concentration of innovations falls after abolishing the DPSM. Furthermore, if the optimal patent policy takes into account the concerns in my analysis, then there may be a *reverse causality*: abstract ideas and basic inventions become patentable *precisely when* there is a better follower joining the development process.

There is a long and well established literature of the doctrine of patentable subject matter in the legal profession.<sup>8</sup> In economics, however, most studies either assume that early inventions always receive patent protection (Green and Scotchmer, 1995, Scotchmer, 1996, Denicolò, 2000), or give equal treatments to innovations at different stages (O'Donoghue, 1998). Matutes *et al.* (1996) and Kultti and Mittunen (2008) allow various levels of protection to the basic invention, including no protection, but conclude that some protection is always better. To the best of my knowledge,

---

<sup>7</sup>See, e.g., Merges (2007) for a discussion of these "unfulfilling" critics in the software industry.

<sup>8</sup>See Merges (1997) for a general discussion. A partial list of recent articles includes Gruner (2007), Kuhn (2007) and Risch (2008).

Harhoff *et al.* (2001) and Aoki and Nagaoka (2004) are the two exceptions that obtain no patent protection to the basic invention as the optimal policy. Assuming that firms have fixed research capacity, Harhoff *et al.* (2001) cautions that patenting basic inventions (gene in their model) may induce socially wasteful stockpile of basic inventions and delay applications. Aoki and Nagaoka (2004) allow firms to vary R&D efforts and is the most relevant paper to my analysis.<sup>9</sup>

Aoki and Nagaoka (2004) considers the same issue as here, namely, whether to grant patent protection to an intermediate invention that serves only as an input for future research, and obtains a pretty intuitive result that patent protection is desirable when conducting basic research is very costly. Aoki and Nagaoka (2004) adopts a two-stage patent race model as in Denicolò (2000), and assume that players have the same Poisson-type innovation technology. In this paper, I stress the asymmetry between inventors of different generations. I will also show that, when the first stage innovation cost has uniform distribution, the optimality of the DPSM does not depend on the cost parameter (the support of the distribution) at this stage. In this regard, my analysis is complementary to the insight derived in Aoki and Nagaoka (2004).

To proceed, section 2 introduces the basic setting; section 3 considers how the patent policy affects the innovation performance at each stage, whose results are applied in Section 4 to determine when it is optimal to enable the DPSM; section 5, to be completed extends the basic model in several directions; and section 6 concludes the paper. Proofs are collected in Appendix A.

## 2 Model

A pioneering inventor (pioneer, she) and a following inventor (follower, he) engage in a two-stage innovation process. The goal of the first stage is to create a basic in-

---

<sup>9</sup>Aoki and Nagaoka (2004) considers the same issue as here but in the name of utility requirement. Arguably there is some over-lapping between the utility requirement and the DPSM: an abstract idea is not patentable because it lacks “specific and substantial utility,” i.e., it is not “useful for any particular practical purpose.” (See USPTO, *Utility Examination Guidelines*, <http://www.uspto.gov/web/menu/utility.pdf>.) Indeed, in *Brenner vs. Manson*, 383 U.S. 519 (1966), the Supreme Court ruled that the Manson patent is at a too preliminary stage to be protected by a patent, and stated that “a patent is not a hunting license. It is not a reward for the search, but compensation for its successful conclusion.” The Court’s reasoning, however, contains some flavor of patent scope: “Unless and until a process is refined and developed to this point—where specific benefit exists in current available form—there is insufficient justification for permitting an applicant to engross what may prove to be a broad field.” Risch (2008) suggests to abolish the DPSM but reinvigorate the utility requirement to assess the patentability of each invention. In practice, the utility requirement is not strictly applied. Few patent applications are rejected under this requirement.

vention or scientific knowledge whose application is to be discovered at the second stage. As in Matutes *et al.* (1996), I assume that only the pioneer participates in the first stage, but both players may search for the application at the second-stage. To compare my results with the cumulative innovation literature, I also assume that, at the second stage, players are looking for the same application, or applications with high substitutability in terms of payoffs. (This assumption is relaxed in Section 5.)

An inventor decides whether to spend an exogenous (but *ex ante* random) innovation cost, and after incurring the cost the invention arrives with some probability. At the first stage, I assume that the basic invention will be created for sure when the pioneering inventor spends the cost  $c_0$ , which is distributed over  $[0, \infty)$  with CDF  $F_0(\cdot)$  and pdf  $f_0(\cdot)$ . The basic invention has no stand-alone value, and the game ends when the pioneer decides not to spend  $c_0$ .

After the pioneer incurs  $c_0$ , the game proceeds to the stage of application search. The application has a private value  $\pi > 0$  and exists with a probability  $\alpha \in (0, 1]$ . The expected value is  $v \equiv \alpha\pi$ . Given existence, the pioneering inventor can find the application after incurring a cost  $c_1 \in [0, \infty)$ . Similarly, the following inventor can find the existing application with a cost  $c_2 \in [0, \infty)$ . Denote the CDF and pdf of cost  $c_i$  as  $F_i(\cdot)$  and  $f_i(\cdot)$ , respectively,  $i \in \{1, 2\}$ . I assume that the pioneering inventor searches first, and the true cost  $c_i$  is the player's private information. An inventor cannot commit to her/his own nor observe the other's search strategy.

To avoid unnecessary complexity, I assume that  $F_i$  as well as  $f_i$  are continuous and differentiable as necessary,  $i \in \{0, 1, 2\}$ . In addition, for all  $i \in \{0, 1, 2\}$ ,  $f_i(c) > 0$  for  $0 \leq c < C_i$ , with  $C_i > v$ . This guarantees that  $0 < F_i(v) < 1$ , and so even if an inventor can grab the whole expected surplus, from the *ex ante* point of view there is some probability that the inventor is not willing to engage in innovation.

In the basic model, I assume that  $\alpha$  is an exogenous variable and observable to both inventors. When performing comparative static analysis with respect to this parameter, I will simultaneously adjust  $\pi$  so that the expected value  $v$  remains the same. The parameter  $\alpha$ , then, captures how "abstract" the basic invention is, or how far it is from commercial applications. A lower  $\alpha$  means that it is more difficult to find or develop the application, although the expected value is not affected. (In Section 5, the pioneer is allowed to influence  $\alpha$ , but we shall maintain the observability assumption.)

As in the literature of cumulative innovation, the patent policy affects the division of surplus  $\pi$  between inventors. To focus on the doctrine of patentable subject matter,

I assume that the application is patentable but always infringes on the basic invention when the latter is protected by the patent rights. The only policy instrument is the level of patent rights rewarded to the basic invention.

If the pioneering inventor discovers the application, then she obtains a patent on the application (and maybe also one on the basic invention); she enjoys the whole surplus  $\pi$ . If the follower makes the discovery, then patent policy determines that the pioneer receives  $\theta\pi$  and the follower receives  $(1 - \theta)\pi$ , where  $\theta \in [0, \bar{\theta}]$  and  $\bar{\theta} < 1$ . A higher  $\theta$  then implies stronger patent rights endowed to the basic invention, and the doctrine of the patentable subject matter corresponds to the case of  $\theta = 0$ . The upper bound  $\bar{\theta}$  is assumed to be strictly less than one because generally, in case of mutual blocking patents, each patent-holder would receive a share of surplus. In other words, I exclude the extreme case where the pioneering inventor has the full bargaining power.

Note that, if the pioneer exhausts her search opportunity but does not come up with the application, i.e. if she decides not to spend  $c_1$  or if  $c_1$  is incurred but she doesn't find the application, then the pioneer is (weakly) better off to disclose the basic invention, for all values of patent policy  $\theta$ . When the DPSM is enabled and the basic invention is not patentable ( $\theta = 0$ ), then whether the pioneer discloses the basic invention has no impact on her payoff. She won't get a share of  $\pi$  whatever happens after.<sup>10</sup> When the basic invention is patentable with  $\theta > 0$ , by disclosing the basic invention and so allow the follower to engage in application search, the pioneer may receive a surplus  $\theta\pi$  with some probability. Since there is no harm of disclosing the basic invention, I rule out the secrecy protection and assume that the pioneer will always publish the basic invention.

The optimal policy  $\theta$  is derived to induce technological progress, as measured by the overall probability to complete the two-stage innovation process.<sup>11</sup> This objective can also be justified from the concern of the social surplus. When the *application* has significant positive externality, private parties always under-invest. It is socially desirable to raise private innovation efforts in order to achieve the application.

Figure 1 illustrates the timing of the game.

- At time 0, the patent policy  $\theta$  is announced;

---

<sup>10</sup>But after disclosure of the basic invention the pioneer may receive, say, a Nobel Prize or other reputation-based reward from the scientific community for the recognition as the inventor of important scientific knowledge or breakthrough.

<sup>11</sup>In Section 4, I show that the DPSM cannot maximize the joint surplus of the two inventors.

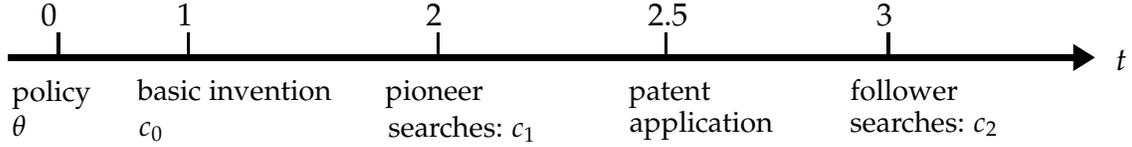

Figure 1: Timing

- at time 1, the pioneer learns the patent policy and the cost  $c_0$  of conducting the first stage innovation. The game continues only if the inventor spends  $c_0$  and creates the basic invention;
- at time 2, the pioneer inventor learns  $c_1$  and decides whether to search the application;
- at time 2.5, the pioneer applies patents for the basic invention (if allowed), and for the application (if she finds it); and
- at time 3, if the pioneer doesn't find the application, then the follower learns his search cost  $c_2$  and decides whether to search.

When the pioneering inventor holds a patent on the basic invention but doesn't find the application, the following inventor may want to negotiate a license before searching for the application. I postpone the discussion of licensing between time 2.5 and time 3 to Section 5.

### 3 The DPSM and Stage-wise Innovation Performance

This section evaluates the impact of patent policy  $\theta$  on the innovation process. Solving the game in the backward manner, suppose that the pioneer has created the basic invention, and consider the subgame of application search.

If the pioneer incurs  $c_1$  and finds the application, then she can patent the application (and maybe the basic invention) and gets the whole surplus  $\pi$ ; the game ends. Suppose that the pioneering inventor does not come up with the application, either because she doesn't spend  $c_1$  to search, or because she incurs  $c_1$  but the application does not exist. By assumption, the follower cannot distinguish between the two events.<sup>12</sup> After learning his search cost  $c_2$ , the follower decides whether to search

---

<sup>12</sup>If the pioneer has incurred search cost but failed to find the application, by assumption it is a clear indication that the application does not exist. This "negative information" is valuable to the follower as well as the society for it prevents further wasteful search effort. But to the extent that the true level of  $c_1$  is the pioneer's private information and whether she has spent this cost is non-verifiable, it is unclear which

with some updated belief  $\hat{\alpha}$  that the application exists. Below I will show that, for both players, the optimal search strategy takes a cut-off form. That is, an inventor will incur the search cost if and only if it is lower than a threshold value. Given this rule, when the follower believes that the pioneer's cut-off is  $\tilde{c}_1$ , his updated belief is

$$\hat{\alpha}(\tilde{c}_1) = \frac{\alpha[1 - F_1(\tilde{c}_1)]}{1 - \alpha + \alpha[1 - F_1(\tilde{c}_1)]} = \frac{\alpha[1 - F_1(\tilde{c}_1)]}{1 - \alpha F_1(\tilde{c}_1)}. \quad (1)$$

With probability  $\alpha$ , the application exists, and the pioneer finds it only if incurring the cost  $c_1$ ; and with probability  $1 - \alpha$ , the application does not exist and the pioneering inventor won't be able to find it whether spending  $c_1$  or not. The follower then updates his belief according to Bayes' rule as expressed in condition (1).

Given the patent policy  $\theta \in [0, \bar{\theta}]$ , the follower receives a payoff  $(1 - \theta)\pi$  for his discovery. He incurs  $c_2$  and searches if and only if

$$\hat{\alpha}\pi(1 - \theta) - c_2 \geq 0 \Rightarrow c_2 \leq \hat{c}_2 \equiv \hat{\alpha}\pi(1 - \theta). \quad (2)$$

The follower adopts a cut-off rule, with an expected payoff (given that the pioneering inventor doesn't find the application)

$$\hat{U}_2 = \int_0^{\hat{c}_2} [\hat{\alpha}\pi(1 - \theta) - c_2] dF_2. \quad (3)$$

For the pioneer, if she spends the cost  $c_1$ , then with probability  $\alpha$  she will find the application and enjoy the whole surplus  $\pi$ ; and with probability  $1 - \alpha$  the application does not exist and the follower will not find it either. If the pioneer does not spend  $c_1$ , then she will receive a surplus  $\theta\pi$  when the application exists and the follower searches. Suppose that the pioneer believes that the follower adopts a cut-off  $\tilde{c}_2$  and so will search with probability  $F_2(\tilde{c}_2)$ . The pioneer searches if and only if

$$\alpha\pi - c_1 \geq F_2(\tilde{c}_2)\alpha\pi\theta \Rightarrow c_1 \leq \hat{c}_1 \equiv \alpha\pi[1 - F_2(\tilde{c}_2)\theta] = v[1 - F_2(\tilde{c}_2)\theta]. \quad (4)$$

The pioneer also adopts a cut-off rule, and her expected payoff at the second-stage is

$$\hat{U}_1 = \int_0^{\hat{c}_1} (\alpha\pi - c_1) dF_1 + [1 - F_1(\hat{c}_1)]F_2(\tilde{c}_2)\alpha\pi\theta. \quad (5)$$

---

patent policy tool could be used to encourage the pioneer to disclosure this information. Furthermore, since patents are public record, whenever the identity of following inventors are unknown *ex ante*, it may be difficult to enforce patent rights that are granted to knowledge that is used to *prevent* some activities from happening. I thus do not consider how the patent system should be designed to directly tackle this issue. (A monetary reward might be useful, though. That is, the pioneering inventor receives a prize in related to the following inventor's expected saving when the former brings the hard evidence that she does spend  $c_1$ . But when the following inventor cannot be traced down to finance the monetary reward, we then go beyond the scope of the patent system and public funds become necessary.) Alternatively, the follower may want to "purchase" this information. Section 5 (to be finished) will consider this "licensing" scenario.

By assumption, players cannot commit to their search strategies, i.e., the cut-off values. Since the true search cost and the decision to incur it are not observable to the other party, the proper equilibrium concept at the search subgame is rational expectation equilibrium. Slightly abusing the notation, a rational expectation equilibrium is a pair of cut-offs  $(\hat{c}_1, \hat{c}_2)$  such that they are determined according to conditions (2) and (4), with the belief  $\hat{a}$  in condition (2) evaluated at  $\tilde{c}_1 = \hat{c}_1$  according to the expression (1), and the belief  $\tilde{c}_2 = \hat{c}_2$  in condition (4). Given a search equilibrium  $(\hat{c}_1, \hat{c}_2)$ , denote the corresponding probabilities  $\hat{F}_i \equiv F_i(\hat{c}_i)$ ,  $i \in \{1, 2\}$ . For the interest of this paper, I denote  $(c_1^*, c_2^*)$  as the search equilibrium under the DPSM, i.e., under the policy  $\theta = 0$ , with corresponding  $F_i^* = F_i(c_i^*)$ ,  $i = 1, 2$ .

The DPSM guarantees a unique search equilibrium. Setting  $\theta = 0$  in condition (4), the pioneer's search decision is independent of the follower's search strategy. The optimal cut-off is uniquely determined by

$$c_1^* \equiv \alpha\pi \equiv v. \quad (6)$$

This unique cut-off then pins down the follower's updated belief at search,  $\hat{a}(c_1^*) \equiv \alpha^*$ , and the follower's optimal cut-off  $c_2^*$ :

$$c_2^* \equiv \alpha^*\pi. \quad (7)$$

When  $\theta > 0$ , the two inventors' search decisions become strategic substitutes. In equilibrium, a higher cut-off  $\hat{c}_1$  will reduce  $\hat{c}_2$ , and *vice versa*. The pioneer, with  $\theta > 0$ , benefits from the follower's search. More intensive search by the follower, i.e., a higher cut-off  $\hat{c}_2$  and so a larger probability  $\hat{F}_2$ , lowers the pioneer's search incentive. The pioneer's cut-off  $\hat{c}_1$  is decreasing in  $\hat{c}_2$  for  $\theta > 0$ .

The negative impact of  $\hat{c}_1$  on  $\hat{c}_2$  works through the belief  $\hat{a}$ . One event leading to the follower's search is the pioneer's failure to find the application, which implies that the application does not exist. The follower's search opportunity, in other words, conveys a bad news that the application is less likely to exist. This pessimistic message becomes worse as the pioneer searches more intensively. For all  $\alpha \in (0, 1)$ , a higher  $\hat{c}_1$  by the pioneer reduces the follower's belief at search:

$$\frac{\partial \hat{a}}{\partial \tilde{c}_1} = -\frac{\alpha(1-\alpha)f_1(\tilde{c}_1)}{[1-\alpha F_1(\tilde{c}_1)]^2} < 0. \quad (8)$$

A negative effect on belief depresses the follower's search incentives:  $\hat{c}_2$  is decreasing in  $\hat{c}_1$ . As long as  $\theta < 1$ , the patent policy only changes the magnitude of this effect, but does not affect its presence.

The mutual dependence of search decisions may lead to multiple search equilibria. Consider an increase in  $\hat{c}_1$ . Along the equilibrium path, a more intensive search from the pioneer lowers the follower's belief, and so the follower's equilibrium cut-off  $\hat{c}_2$ . A lower search intensity from the follower in turn justifies the initial increase in  $\hat{c}_1$ . By the same token, expecting an increase of the follower's cut-off, the pioneer will search over a smaller range of search cost. The follower, along the equilibrium path, will have a higher updated belief, and so is willing to raise the cut-off.

Despite the possibility of multiple equilibria under  $\theta \in (0, \bar{\theta}]$ , granting patent rights to the basic invention always reduces the pioneer's search incentive,  $c_1^* > \hat{c}_1$  for all  $\theta$  such that  $0 < \theta \leq \bar{\theta} < 1$ . By  $\bar{\theta} < 1$ , in any search equilibrium  $\hat{c}_2 > 0$  and so  $\hat{F}_2 > 0$ . It follows that  $c_1^* = v > \hat{c}_1 = v(1 - \hat{F}_2\theta)$ , for all  $\theta \in (0, \bar{\theta}]$ . For the follower, a lower cut-off adopted by the pioneer boosts his belief at search:  $\hat{\alpha}(\hat{c}_1) > \alpha^*$ , for all  $\hat{c}_1 < c_1^*$ . Whether  $\hat{c}_2 \geq c_2^*$  then depends on whether  $\hat{\alpha}(1 - \theta) \geq \alpha^*$ . In this model, the negative effect of transferring surplus  $\theta\pi$  from the follower to the pioneer on the former's search incentive is mitigated by the opposite effect on the belief. Patent protection to the basic invention does not necessarily weaken the follower's search incentives.

Given the parameter  $\alpha$  and search equilibrium  $(\hat{c}_1, \hat{c}_2)$ , the probability to discover the application is  $\alpha[\hat{F}_1 + (1 - \hat{F}_1)\hat{F}_2]$ . Define  $\hat{E} \equiv \hat{F}_1 + (1 - \hat{F}_1)\hat{F}_2$ , which measures the overall search effort, or the innovation performance at the second stage. Define the corresponding measure under the DPSM as  $E^* \equiv F_1^* + (1 - F_1^*)F_2^*$ . Since  $c_1^* > \hat{c}_1$ , the comparison between  $E^*$  and  $\hat{E}$  depends on the relative size of  $c_2^*$  and  $\hat{c}_2$ . If  $c_2^* \geq \hat{c}_2$ , then the DPSM surely boosts the second-stage innovation performance,  $E^* > \hat{E}$ . If  $\hat{c}_2 \gg c_2^*$ , however, we may have the opposite outcome,  $\hat{E} > E^*$ . Different from Aoki and Nagaoka (2004), in my model patent protection to the basic invention is not necessarily detrimental to the second stage innovation performance. The following example use two-point search technology to illustrate this point, as well as the possibility of multiple search equilibria.

*Example 1.* (Two-point search technology). Suppose that both the pioneer's and follower's search cost have two-point distributions,  $c_i \in \{C_i, K\}$ , with  $K > v \geq C_i \geq 0$ , and the probability of low search cost is  $\Pr(c_i = C_i) = p_i \in (0, 1)$ ,  $i = 1, 2$ . An inventor will not incur the high search cost  $K > v$ . In any search equilibrium, the pioneer's (follower's) search probability is at most  $\hat{F}_1 = p_1$  ( $\hat{F}_2 = p_2$ , respectively).

Fixing  $\theta > 0$ , I first show that both  $(\hat{F}_1, \hat{F}_2) = (0, p_2)$  and  $(p_1, 0)$  can be search equi-

libria. To have  $(0, p_2)$  as the equilibrium, the pioneer must find it too costly to incur  $C_1$ , given that the following inventor will incur  $C_2$ . We need  $C_1 > v(1 - p_2\theta)$ . And for the follower to be willing to incur  $C_2$ , given that the pioneering inventor does not search at all, we need  $C_2 \leq v(1 - \theta)$ . In this search equilibrium, the follower's belief maintains at the *ex ante* level. For  $(p_1, 0)$  to be the search equilibrium, the pioneer incurs  $C_1$  but the follower will not search. We need  $C_1 \leq v$  and  $C_2 > \hat{\alpha}\pi(1 - \theta)$ , where  $\hat{\alpha} = \alpha(1 - p_1)/(1 - \alpha p_1) < \alpha$ . We have multiple equilibria when

$$v(1 - p_2\theta) < C_1 \leq v \text{ and } \hat{\alpha}\pi(1 - \theta) < C_2 \leq v(1 - \theta). \quad (9)$$

An implication of multiple equilibria is mis-allocation of search activity. Even though the overall search performance is the same, different equilibria may entail different levels of total search cost. To see this, suppose  $p_1 = p_2 = p \in (0, 1)$  and condition (9) holds. Both search equilibria have the same probability to find the application (given existence),  $\hat{E} = p$ , but different search costs depending on which inventor searches. When  $C_1 > C_2$ , then the equilibrium where only the follower searches is more cost-efficient. In fact, if  $p_2 > p_1$ , then this equilibrium also has a higher probability to find the application.

Lastly, suppose that  $p_2 > p_1$ . Under the DPSM ( $\theta = 0$ ), the search equilibrium is unique,  $(p_1, 0)$ , with  $E^* = p_1$ . But if we let the basic invention be patentable with  $\theta > 0$  such that condition (9) holds, then in the search equilibrium  $(0, p_2)$ , we have  $\hat{E} = p_2 > E^*$ . Patenting the basic invention boosts the second stage innovation performance when the “good” search equilibrium prevails. ||

The following proposition summarizes the results concerning the second stage and provides comparative static analysis with respect to  $\theta$  and  $\alpha$ . Recall that, when considering a marginal change in  $\alpha$ , I will keep the expected value  $v \equiv \alpha\pi$  constant.

*Proposition 1. (Search equilibrium). When  $\theta \in (0, \bar{\theta}]$  and  $\alpha \in (0, 1)$ , there may be multiple search equilibria at the second innovation stage. But the search equilibrium is unique under the DPSM.*

*The pioneer has a higher search incentive under the DPSM than under other policy  $\theta \in (0, \bar{\theta}]$ ,  $c_1^* > \hat{c}_1$ . The impact of the patent policy on the follower's search incentive is ambiguous,  $c_2^* \gtrless \hat{c}_2$ .*

*Consider stable search equilibria. For the overall search performance,  $E^*$  and  $\hat{E}$ :*

- *For  $\theta > 0$ ,  $d\hat{E}/d\theta \gtrless 0$ , but not both  $d\hat{c}_1/d\theta$  and  $d\hat{c}_2/d\theta > 0$ . When evaluated at  $\theta = 0$ ,  $d\hat{c}_1/d\theta < 0$ .*

- Under the DPSM,  $dE^*/d\alpha > 0$ . But when  $\theta > 0$ ,  $d\hat{c}_1/d\alpha < 0$  and  $d\hat{c}_2/d\alpha > 0$  and so  $d\hat{E}/d\alpha \geq 0$ .

Suppose that  $c_i$  is distributed uniformly over the range  $[0, \gamma_i v]$ , for  $\gamma_i > 1$  and  $i \in \{1, 2\}$ . Given  $\theta > 0$ ,  $d\hat{E}/d\alpha < 0$  when  $\gamma_1 < 1 + \theta$  and  $\gamma_2[(1 + \theta) - \gamma_1] > 1/2$ .

*Remark 1.* (Market structure). An important difference between my model and the analytical framework adopted by Aoki and Nagaoka (2004) is the effect of the patent policy  $\theta$  on the “market structure” of the innovation market. Aoki and Nagaoka (2004) uses a two-stage patent race model from Denicolò (2000) and also allows the first inventor to engage in the second stage innovation.<sup>13</sup> Due to the assumptions of a homogeneous Poisson race and identical research capability, if the basic invention is patentable, the patent-holder has no incentive to let other inventors pursue the second stage innovation. The only meaningful policy space is a binary set, namely, whether the basic invention is patentable or not. The pioneer does not benefit from other inventor’s innovation capacity. Patenting the basic invention generates a monopoly at the second stage, and increases the concentration of the innovation activity, i.e., the extent to which different inventions are created by different inventors.

By contrast, I have a “hybrid” structure where the pioneer enjoys head-start advantage at the second stage and at the same time could extract some surplus from the follower when the basic invention is patentable and her search fails. My model has a richer policy space  $\theta \in [0, \bar{\theta}]$ , and can easily incorporate asymmetric innovation capacities by different inventors, as captured by different distributions  $F_1$  and  $F_2$ . In addition, granting the patent protection to the basic invention may reduce the concentration of the innovation market. Given that the second stage innovation is completed, the probability that it is finished by the follower is  $[(1 - F_1^*)F_2^*]/E^*$  when the basic invention is not patentable, and  $[(1 - \hat{F}_1)\hat{F}_2]/\hat{E}$  when it is patentable with  $\theta > 0$ . Compare the two levels,

$$\frac{(1 - \hat{F}_1)\hat{F}_2}{\hat{E}} > \frac{(1 - F_1^*)F_2^*}{E^*} \Leftrightarrow F_1^*(1 - \hat{F}_1)\hat{F}_2 > \hat{F}_1(1 - F_1^*)F_2^*. \quad (10)$$

Since  $F_1^* > \hat{F}_1$ , as long as  $\hat{F}_2$  is not too small relative to  $F_2^*$ , patenting the basic invention helps the decentralization of innovation activities. ||

Turn to the first stage. Expecting a payoff  $U_1$  from the search subgame, the pioneer will incur a cost  $c_0$  to create the basic invention as long as  $c_0 \leq U_1$ . The basic inven-

---

<sup>13</sup>They assume free entry at the first stage. The “pioneer,” therefore, refers to the first inventor to finish the race and create the basic invention (or the intermediate technology as they called).

tion will be produced with a probability  $F_0(U_1)$ , and a higher  $U_1$  raises the pioneer's incentive to engage in basic research. The pioneer's expected payoff at the first stage is

$$\hat{U}_0 = \int_0^{U_1} (U_1 - c_0) dF_0. \quad (11)$$

Denote  $\hat{U}_1$  and  $U_1^*$  as the pioneer's payoffs in the search equilibrium when  $\theta \in (0, \bar{\theta}]$  and  $\theta = 0$ , respectively. By previous discussion,  $c_1^* > \hat{c}_1$  and  $\hat{c}_2 > 0$ . Together with the definition of  $\hat{c}_1$ ,

$$\begin{aligned} U_1^* &= \int_0^{c_1^*} (v - c_1) dF_1 = \int_0^{\hat{c}_1} (v - c_1) dF_1 + \int_{\hat{c}_1}^{c_1^*} (v - c_1) dF_1 \\ &< \int_0^{\hat{c}_1} (v - c_1) dF_1 + \int_{\hat{c}_1}^{c_1^*} \hat{F}_2 v \theta dF_1 < \hat{U}_1 = \int_0^{\hat{c}_1} (v - c_1) dF_1 + (1 - \hat{F}_1) \hat{F}_2 v \theta. \end{aligned} \quad (12)$$

As in the standard cumulative innovation literature, denying patent protection to the basic invention reduces the pioneer's first stage incentive. The DPSM imposes a cost of harming the basic innovation.

*Proposition 2. (First stage innovation incentives). Granting patent protection to the basic invention increases the pioneer's incentive to engage in basic research.*

## 4 When to Impose the DPSM?

Considering the impact on both innovation stages, when is it optimal to impose the DPSM? Using the overall technology progress rate,  $F_0(\hat{U}_1) \alpha \hat{E}$ , as the policy criterion, I am interested in situations where  $\theta = 0$  is the solution to the program  $\max_{\theta} \alpha F_0(\hat{U}_1) \hat{E}$ . Fixing  $\alpha$ , it is equivalent to finding conditions such that  $F_0(U_1^*) E^* \geq F_0(\hat{U}_1) \hat{E}$  for all  $\theta \in (0, \bar{\theta}]$ .

By previous analysis,  $U_1^* < \hat{U}_1$  and so the DPSM is detrimental to the first stage innovation incentive. If, at the second stage,  $E^* < \hat{E}$  for some  $\theta \in (0, \bar{\theta}]$ , then the DPSM is dominated at both stages of the innovation process. A necessary condition to reject patent protection to the basic invention therefore is  $\hat{E} < E^*$  for all  $\theta \in (0, \bar{\theta}]$ . Suppose that this necessary condition holds. That is, the indirect effect of  $\theta > 0$  on the follower's belief,  $\hat{\alpha}(\hat{c}_1) > \alpha^*$ , is not large enough to dominate the sum of the effect on the pioneer's search decision ( $c_1^* > \hat{c}_1$ ) and the direct effect on the follower's search incentive due to surplus transfer.

Consider the overall impact of the patent policy on the technological progress:

$$\begin{aligned}
\frac{dF_0(\hat{U}_1)\hat{E}}{d\theta} &= \hat{E}f_0(\hat{U}_1)\frac{d\hat{U}_1}{d\theta} + F_0(\hat{U}_1)\frac{d\hat{E}}{d\theta} \\
&= \hat{E}f_0(1 - \hat{F}_1)v \left( \hat{F}_2 + \theta\hat{f}_2\frac{d\hat{c}_2}{d\theta} \right) + F_0(1 - \hat{F}_1)(1 - \hat{F}_2) \left( \frac{\hat{f}_1}{1 - \hat{F}_1}\frac{d\hat{c}_1}{d\theta} + \frac{\hat{f}_2}{1 - \hat{F}_2}\frac{d\hat{c}_2}{d\theta} \right) \quad (13) \\
&= (1 - \hat{F}_1) \left[ \hat{E}f_0v \left( \hat{F}_2 + \theta\hat{f}_2\frac{d\hat{c}_2}{d\theta} \right) + F_0(1 - \hat{F}_2) \left( \frac{\hat{f}_1}{1 - \hat{F}_1}\frac{d\hat{c}_1}{d\theta} + \frac{\hat{f}_2}{1 - \hat{F}_2}\frac{d\hat{c}_2}{d\theta} \right) \right].
\end{aligned}$$

In my model, the patent policy affects three decisions: besides the pioneer's innovation decision at the first stage and the follower's decision at the second stage, it also affects the pioneer's incentive at the second stage. The cumulative innovation literature, such as Green and Scotchmer (1995), emphasizes the trade-off between different generations of inventors at different innovation stages, but overlooks the *same* inventor's innovation incentives across stages. As shown in Section 3, a patent on the basic invention encourages the first stage innovation ( $F_0(\hat{U}_1) > F_0(U_1^*)$ ) and changes the follower's innovation performance ( $d\hat{c}_2/d\theta \geq 0$ ). This early reward also *discourages* the pioneer from continuing her research activity ( $\hat{F}_1 < F_1^*$ ). When this effect is strong enough, we may find a reason to reject patenting the basic invention.

To better illustrate the key result, I make a few simplifications on the cost distributions. Suppose that  $c_0$  follows the uniform distribution over the support  $[0, \gamma_0 v]$ , with  $\gamma_0 > 1$ , and  $c_2$  follows the two-point distribution,  $c_2 \in \{0, K\}$ , with  $K > v$  and  $\Pr(c_2 = 0) = p_2 \in (0, 1)$ . The first simplification brings about an interesting case where the optimal policy  $\theta$  is independent of the cost parameter at the first stage, namely,  $\gamma_0$ . Different from Aoki and Nagaoka (2004), within the class of uniform distributions, I can derive the optimality of the DPSM without referring to the difficulty of obtaining the basic invention. The two-point search technology,  $c_2 \in \{0, K\}$ , implies that the follower has a fixed probability  $\hat{F}_2 = F_2^* = p_2$  to find the application. The second simplification is introduced to point out how the follower's capacity  $p_2$  affects the trade-off between the pioneer's innovation incentives at different stages.<sup>14</sup>

---

<sup>14</sup>Suppose that, instead, the pioneer has a fixed search capacity,  $c_1 \in \{0, K\}$  with  $\Pr(c_1 = 0) = p_1 \in [0, 1)$ . The optimal  $\theta$  then is determined according to the classical trade-off between different inventor's incentives at different stages. (When  $p_1 = 0$ , it corresponds to the standard model where different generations of innovations are conducted by different players.) By  $d\hat{c}_1/d\theta = 0$  and so  $d\hat{c}_2/d\theta = -v\phi$ , where  $\phi = (1 - \hat{F}_1)/(1 - \alpha\hat{F}_1)$ ,

$$\text{sign} \left( \frac{dF_0(\hat{U}_1)\hat{E}}{d\theta} \right) = \text{sign} \left( \frac{f_0}{F_0} [p_1 + (1 - p_1)\hat{F}_2] (\hat{F}_2 - \theta\phi\hat{f}_2) - \hat{f}_2\phi \right). \quad (14)$$

Under these specifications,  $d\hat{c}_2/d\theta = 0$  and  $d\hat{c}_1/d\theta = -vp_2$ . Fixing the follower's search capacity, stronger patent protection to the basic invention  $\theta$  always raises the pioneer's incentive to engage in basic invention. By integration by parts and the optimal cut-off  $\hat{c}_1 = v(1 - \hat{F}_2\theta) = v(1 - p_2\theta)$ ,

$$\begin{aligned}\hat{U}_1 &= \int_0^{\hat{c}_1} (v - c_1)dF_1 + (1 - \hat{F}_1)p_2v\theta = (v - c_1)F(c_1)|_0^{\hat{c}_1} + \int_0^{\hat{c}_1} F_1dc_1 + (1 - \hat{F}_1)p_2v\theta \\ &= \int_0^{\hat{c}_1} F_1dc_1 + p_2v\theta,\end{aligned}\tag{16}$$

and so

$$\frac{d\hat{U}_1}{d\theta} = \hat{F}_1 \frac{d\hat{c}_1}{d\theta} + p_2v = (1 - \hat{F}_1)p_2v > 0, \text{ when } \hat{F}_1 < 1.\tag{17}$$

This positive effect, however, comes at a cost of lower second stage innovation performance,

$$\frac{d\hat{E}}{d\theta} = (1 - p_2)\hat{f}_1 \frac{d\hat{c}_1}{d\theta} = -(1 - p_2)\hat{f}_1 p_2v < 0.\tag{18}$$

The term  $p_2v$  appear in both  $d\hat{U}_1/d\theta$  and  $d\hat{E}/d\theta$ . Raising patent protection to the basic invention directly affects the surplus transfer from the follower to the pioneer. Its impact is proportional to the follower's expected return from search, which is  $p_2v$  in this case. Beyond this common factor, we can see that the positive effect on the first stage innovation is also proportional to  $1 - \hat{F}_1$ , the probability that the pioneer finds the application (given existence). For the pioneer will use the patent on the basic invention to get a share of the follower's search surplus only when her search fails. On the other hand, the negative impact on the second stage innovation is also proportional to  $1 - p_2$ , namely, a lower search effort from the pioneer becomes a more serious problem when the follower is less likely to make the discovery. Combining the two factors, it might be optimal to maintain the DPSM and not granting patent rights to the basic invention when the pioneer has significant search capacity (and so  $\hat{F}_1$  is high for all  $\theta \in [0, \bar{\theta}]$ ), but not the follower (and so  $p_2$  is small).

---

If both  $f_0$  and  $f_2$  take uniform distributions, the sign of  $dF_0(\hat{U}_1)\hat{E}/d\theta$ , when evaluated at  $\theta = 0$ , is the same as

$$\frac{1}{p_1v}[p_1 + (1 - p_1)F_2^*] - \frac{\phi}{\phi v} = \frac{1}{v} \left( 1 + \frac{1 - p_1}{p_1} F_2^* - 1 \right) > 0.\tag{15}$$

The DPSM is never optimal.

Under the specified distributions of  $c_0$  and  $c_2$ , the sign of the first-order condition,  $dF_0(\hat{U}_1)\hat{E}/d\theta$ , is the same as

$$\hat{E}(1 - \hat{F}_1) - \hat{U}_1(1 - p_2)\hat{f}_1. \quad (19)$$

The first term,  $\hat{E}(1 - \hat{F}_1)$ , captures the incentive effect of an increase in  $\theta$  on the pioneer's willingness to engage in the first stage research,  $\hat{U}_1$ . The second term,  $\hat{U}_1(1 - p_2)\hat{f}_1$ , is associated with the effect of  $\theta$  on the the pioneer's second stage decision  $\hat{c}_1$ . If the expression (19) is negative for all  $\theta \in [0, \bar{\theta}]$ , then the DPSM is the optimal policy.

To illustrate how the optimality of the DPSM is determined by the pioneer's search capacity, let's assume that  $c_1$  also has uniform distribution over the support  $[0, \gamma_1 v]$ , with  $\gamma_1 > 1$ . When  $\gamma_1$  is smaller, the support of  $c_1$  shrinks, the pioneer is more likely to have smaller search cost. Fixing  $\hat{c}_1$ , the pioneer is more likely to make the discovery,  $\hat{F}_1$  is decreasing in  $\gamma_1$ . This parameter also affects the density function  $f_1(c_1) = 1/\gamma_1 v$ . A reduction in  $\gamma_1$  increases  $f_1$ , provided that  $c_1 \in [0, \gamma_1 v]$ , which in turn magnifies the negative impact of  $\theta$  on  $\hat{F}_1$  and thus  $\hat{E}$ . A lower  $\gamma_1$ , then, implies a better search capacity by the pioneer, and so the more likely to find the DPSM optimal.

After some calculation,

$$\hat{U}_1 = \frac{v}{2\gamma_1} [1 + 2(\gamma_1 - 1)\theta p_2 + (\theta p_2)^2]. \quad (20)$$

The sign of the first-order condition is the same as

$$\begin{aligned} & 2(\gamma_1 - 1)[(\gamma_1 - 1)p_2 + 1] - (1 - p_2) - 3(1 - p_2)(p_2\theta)^2 \\ & + 2p_2\theta[(\gamma_1 - 1)p_2 + 1 - 2(\gamma_1 - 1)(1 - p_2)]. \end{aligned} \quad (21)$$

When  $\gamma_1 \rightarrow 1^+$  and  $p_2 \rightarrow 0$ , the first-order condition is strictly negative for all  $\theta \in [0, \bar{\theta}]$ . The DPSM is the optimal policy. In the proof of the following proposition, I consider the case where  $c_2$  also has a uniform distribution,  $f_2 = 1/(\gamma_2 v)$ , with  $\gamma_2 > 1$ . In this case,  $p_2$  is no more fixed, but the DPSM is optimal when  $\gamma_2$  is large enough and  $\gamma_1$  small enough. As the pioneer's search capacity expands, but the follower's capacity shrinks, denying patent protection to the basic invention is more likely to be optima.

*Proposition 3. Fix  $\alpha$ . To promote the technology progress, a necessary condition for the DPSM to be the optimal policy is that it encourages the overall efforts to search the application,  $E^* > \hat{E}$ , for all  $\theta > 0$ .*

*Suppose that  $c_i$  following uniform distribution,  $f_i = 1/(\gamma_i v)$ , with  $\gamma_i > 1$ ,  $i \in \{0, 1, 2\}$ . The DPSM is an optimal policy when  $\gamma_1$  is small enough and  $\gamma_2$  is large enough.*

In light of this result, the DPSM should be applied, and the basic invention should not be patentable when the pioneer has superior technology at the subsequent research stage, but not the follower. But where does this persistence of innovation dominance come from? One source of this advantage would be some knowledge the pioneer acquired during the first stage. The follower cannot benefit from this knowledge either because of its tacit nature and so the intrinsic difficulty to transfer among different inventors, or the pioneer's unwillingness to disclose and help the follower to understand this knowledge. The former in turn may relate to the landscape of the research environment, for instance, how easily it would be for a late-comer to digest the knowledge required to effectively participation in the innovation process. To the extent that, at its nascent phase, the background information of a field may not be widely distributed, but rather concentrated on very few key players, there may not be many capable followers who can readily pursue the pioneer's research line. The insight of Proposition 3 suggests that patents shouldn't be granted to basic inventions in order to maintain the pioneer's continuation effort. The latter, on the other hand, may depend on the disclosure requirement of the patent law. That is, when weak disclosure or enablement requirements significantly hampers other parties' ability to exploit the patented technology, the patent should not be granted. Although it is a common argument that patent system should be designed to diffuse technology, the reasoning here is based on a somewhat reason, namely, the pioneer's incentive to continue doing research.

Another factor that would affect the pioneer's and follower's chance to develop the application are their commercialization capacity. Although the model is developed as a two-stage innovation process, the second stage can be equivalently interpreted as one that involves not research, but commercialization activity. A party is more likely to successfully commercialize the basic invention if, say, she controls more key physical assets used to develop useful and marketable application. The assumption that the second stage result is patentable then corresponds to the protection to (tangible) property rights. And the condition identified in Proposition 3 implies that the patentability of basic invention hinges on the degree of vertical integration. It should not be patentable when the upstream pioneer extends her dominance to the downstream stage of commercialization.

*Remark 2.* (Alternative objective). This remark considers another objective function, namely, the joint surplus between the two inventors. It turns out that setting  $\theta = 0$  will not maximize the joint surplus. In the search of the optimality of the DPSM, this justifies the use of technology progress as the policy objective.

Given the policy  $\theta$  and the payoffs from the search subgame,  $\hat{U}_1$  and  $\hat{U}_2$ , the joint surplus is

$$S = \int_0^{\hat{U}_1} (\hat{U}_1 - c_0) dF_0 + F_0(\hat{U}_1)(1 - \alpha\hat{F}_1)\hat{U}_2. \quad (22)$$

Since the basic invention has no stand-alone value, when the pioneer is willing to incur  $c_0$ , she expects a payoff  $\hat{U}_1$  from the subsequent subgame. And the follower gets a payoff  $\hat{U}_2$  only when the basic invention is created and the pioneer does not come up with the application. In the proof of Proposition 4, I show that, when evaluating at  $\theta = 0$ , a marginal increase in  $\theta$  always raises the joint surplus  $S$ . This result does not need further restrictions on the distributions of innovation costs. Intuitively, raising  $\theta$  beyond zero only exerts a negative impact on the follower's payoff  $\hat{U}_2$ . This negative effect, however, is canceled by a positive impact on the pioneering inventor's payoff  $\hat{U}_1$ . Therefore, the DPSM cannot be justified with the inventor's joint surplus as the policy objective.

*Proposition 4.* To maximize the joint surplus of the two inventors, it is never optimal to impose the DPSM. ||

## 5 Extensions (to be completed)

**Licensing:**

**Multiple applications:**

**Endogenous search capacity:**

**Endogenous  $\alpha$ :** Although patenting the basic invention encourages basic innovation, the policy impact differs for different values of  $\alpha$ , i.e., how abstract, or the extent to which the basic invention can be readily exploited for actual application. Fix the expected value  $v = \alpha\pi$ . Under the DPSM the pioneer's payoff  $U_1^*$  is independent

of  $\alpha$ . When conducting the basic research, the pioneer is indifferent to the level of  $\alpha$ . But for  $\theta \in (0, \bar{\theta}]$ , by Proposition 1, her payoff is increasing in  $\alpha$ :

$$\frac{d\hat{U}_1}{d\alpha} = (v - \hat{c}_1)\hat{f}_1 \frac{d\hat{c}_1}{d\alpha} - \hat{f}_1 \hat{F}_2 v \theta \frac{d\hat{c}_1}{d\alpha} + (1 - \hat{F}_1)v\theta \hat{f}_2 \frac{d\hat{c}_2}{d\alpha} = (1 - \hat{F}_1)v\theta \hat{f}_2 \frac{d\hat{c}_2}{d\alpha} > 0. \quad (23)$$

Knowing that the basic invention is patentably, the pioneer would prefer a less abstract basic invention, so that the follower is more willing to search for the application. Proposition 1 shows that a higher  $\alpha$  does not always enhance the second stage innovation performance. By the strategic substitution between the two players' search decision, a higher  $\alpha$  will raise  $\hat{c}_2$ , which will in turn reduce  $\hat{c}_1$ . The net effect maybe  $d\hat{E}/d\alpha < 0$  and so a lower successful probability at the second stage. In this case, allowing the basic invention to be patentable may generate a tension between socially and privately optimal level of  $\alpha$ . The pioneer may choose  $\alpha$  that is higher than the socially optimal level.

□ **Endogenous order to search:** In the basic model I let the pioneer search first. An implicit assumption is that the pioneer can protect the basic invention under secrecy until her search fails, or until she decides not to search. This assumption captures some first-mover advantage and, more importantly, avoids the extreme situation where the pioneer is "forced" to disclose the basic invention even if it is *not* patentable. Here I consider whether the pioneer will exploit this advantage, or instead will want to wait until after the follower's search.

I keep the assumption that a player cannot observe the other's true search cost nor the decision to incur the cost, and that the pioneer still learns the trust cost at time 2, but add an additional stage, time 4, where the pioneering inventor can spend her cost  $c_1$  to search, if she hasn't done that at time 2. For a policy  $\theta \in [0, \bar{\theta}]$ , denote  $\hat{c}_1$  and  $\hat{c}_2$  as the equilibrium cut-offs without time 4. I derive conditions under which this additional timing is irrelevant.

When endowed with this additional timing to search, the pioneer knows that if she delays search, she will need to incur  $c_1$  only if the follower doesn't come up with an application. Similar to the reasoning in section 3, the pioneer can update her belief about  $\alpha$  at this event. The pioneer's updated belief at time 4 is  $\alpha \cdot \hat{\phi}$ , where

$$\hat{\phi} = \frac{1 - F_2(\hat{c}_2)}{1 - \alpha F_2(\hat{c}_2)}. \quad (24)$$

Since the follower holds no claim again the pioneer, the latter will incur search at time 4 as long as  $c_1 \leq \alpha \hat{\phi} \pi = \hat{\phi} v$ . For  $c_1 > \hat{\phi} v$ , this additional timing to search is irrelevant.

Suppose that the pioneer has search cost  $c_1 \leq \hat{\phi}v$ . If she searches at time 2, the expected payoff is  $v - c_1$ . If she delays to time 4, the expected payoff is

$$F_2(\hat{c}_2)\theta v + [1 - \alpha F_2(\hat{c}_2)](\hat{\phi}v - c_1) = F_2(\hat{c}_2)\theta v + [1 - F_2(\hat{c}_2)]v - [1 - \alpha F_2(\hat{c}_2)]c_1. \quad (25)$$

When  $F_2(\hat{c}_2) > 0$ ,

$$v - c_1 \geq F_2(\hat{c}_2)\theta v + (1 - F_2(\hat{c}_2))v - [1 - \alpha F_2(\hat{c}_2)]c_1 \Leftrightarrow c_1 \leq (1 - \theta)\pi. \quad (26)$$

For  $c_1$  smaller than  $(1 - \theta)\pi$ , the pioneer will search at time 2 rather than wait.

Compare the pioneer's different thresholds. If

$$1 - \theta \geq \alpha \hat{\phi} = \alpha \frac{1 - F_2(\hat{c}_2)}{1 - \alpha F_2(\hat{c}_2)} \Rightarrow \theta \leq \frac{1 - \alpha}{1 - \alpha F_2(\hat{c}_2)}, \quad (27)$$

then time 4 is irrelevant. The pioneer will even search at time 4 only for  $c_1 \leq \alpha \hat{\phi}\pi$ . But by  $1 - \theta \geq \alpha \hat{\phi}$ , and so  $c_1 \leq (1 - \theta)\pi$ , for this range of search cost the pioneer prefers searching at time 2 than time 4.<sup>15</sup> When  $\alpha$  and  $\theta$  are not too large, such that condition (27) holds, previous results are robust to the pioneer's endogenous search timing.

If condition (27) fails, then the search equilibrium is not robust to the pioneer's additional search opportunity. The pioneer will want to delay search for  $c_1 \in ((1 - \theta)\pi, \hat{\phi}v]$ , and only spend  $c_1 \leq (1 - \theta)\pi$  at time 2. The search equilibrium is characterized by three cut-offs:  $c'_1 = (1 - \theta)\pi$ ,  $c'_2 = \hat{\alpha}(c'_1)\pi(1 - \theta)$ , and  $c''_1 = \hat{\phi}(c'_2)v$ , where

$$\hat{\alpha}(c'_1) = \frac{\alpha[1 - F_1(c'_1)]}{1 - \alpha F_1(c'_1)} \quad \text{and} \quad \hat{\phi}(c'_2) = \frac{1 - F_2(c'_2)}{1 - \alpha F_2(c'_2)}. \quad (28)$$

That is, the pioneer adopts the cut-off  $c'_1$  at time 2, and cut-off  $c''_1$  at time 4, and the follower adopts cut-off  $c'_2$ . The search equilibrium is unique, but the patent policy has similar impact as before. An increase in  $\theta$  will decrease  $c'_1$ , and has a direct negative impact on  $c'_2$ . But a lower  $c'_1$  exerts a positive indirect effect on  $c'_2$  via the follower's belief  $\hat{\alpha}$ . The net change in  $c'_2$ , then, has an opposite effect on the pioneer's second cut-off  $c''_1$  through  $\hat{\phi}$ . The overall impact on the search performance, again, is ambiguous.

## 6 Conclusion

In this paper, I provided a simple theory about the patentability of basic inventions.

I found both necessary conditions and a sufficient condition for the DPSM to be the

---

<sup>15</sup>The same condition also guarantees  $(1 - \theta)\pi \geq \hat{c}_1 = \alpha\pi[1 - \theta F_2(\hat{c}_2)]$ , the cut-off obtained in section 3. That is, the additional time 4 expands the range of search cost the pioneer is willing to spend at time 2. Time 4, again, is irrelevant.

optimal policy. Necessary conditions, i.e., the strong externality of the application and the DPSM's positive effect on the second stage innovation, are derived in a fairly general situation. The sufficient condition concerning the research capacities of the pioneer and follower at the second stage, however, is obtained under specific cost distributions. A future task is to test its robustness in more general settings.

A few other avenues for future research come to mind: multiple pioneers at the first stage innovation as in Denicolò (2000) and Aoki and Nagaoka (2004); secrecy protection to the basic invention; and the combination of the DPSM with other policy instruments, such as patent length and protection to second stage inventions, to name a few. A better understanding of the doctrine of the patentable subject matter would advance our knowledge on the optimal design of the patent system. This paper constitutes an early step.

## Appendix: Proofs

### A Proofs

#### □ Proposition 1

*Proof.* For the comparative static results, keep  $v \equiv \alpha\pi$  constant and denote  $\phi \equiv (1 - \hat{F}_1)/(1 - \alpha\hat{F}_1)$ . Differentiate conditions (2) and (4):

$$d\hat{c}_1 + \theta v \hat{f}_2 d\hat{c}_2 = -v \hat{F}_2 d\theta \quad (29)$$

$$-(1 - \theta)v \frac{\partial \phi}{\partial \hat{c}_1} d\hat{c}_1 + d\hat{c}_2 = -v \phi d\theta + (1 - \theta)v \frac{\partial \phi}{\partial \alpha} d\alpha, \quad (30)$$

where

$$\frac{\partial \phi}{\partial \hat{c}_1} = -\frac{\hat{f}_1(1 - \alpha)}{(1 - \alpha\hat{F}_1)^2} \leq 0 \quad \text{and} \quad \frac{\partial \phi}{\partial \alpha} = \frac{\hat{F}_1(1 - \hat{F}_1)}{(1 - \alpha\hat{F}_1)^2} > 0, \quad (31)$$

with  $\hat{f}_i \equiv f(\hat{c}_i)$ ,  $i \in \{1, 2\}$ .

On the  $c_1 - c_2$  plane, a stable equilibrium  $(\hat{c}_1, \hat{c}_2)$  requires that the pioneer's reaction curve have a larger slope (in absolute value) than the follower's reaction curve. That is,

$$\left| \frac{\partial \hat{c}_2}{\partial \hat{c}_1} \right|_{\hat{c}_1} > \left| \frac{\partial \hat{c}_2}{\partial \hat{c}_1} \right|_{\hat{c}_2} \Leftrightarrow \Delta \equiv 1 + \theta(1 - \theta)v^2 \hat{f}_2 \frac{\partial \phi}{\partial \hat{c}_1} = 1 - \theta(1 - \theta)v^2 \frac{(1 - \alpha)\hat{f}_1 \hat{f}_2}{(1 - \alpha\hat{F}_1)^2} > 0. \quad (32)$$

Suppose that this is true.

By Cramer's rule, the impact of an exogenous change in  $\theta$  are

$$\frac{d\hat{c}_1}{d\theta} = \frac{v}{\Delta}(v\theta\phi\hat{f}_2 - \hat{F}_2) \geq 0 \text{ and } \frac{d\hat{c}_2}{d\theta} = \frac{v}{\Delta}[-(1-\theta)v\hat{F}_2\frac{\partial\phi}{\partial\hat{c}_1} - \phi] \geq 0. \quad (33)$$

When  $\theta = 0$ ,  $d\hat{c}_1/d\theta < 0$ . When  $\theta > 0$ , if both terms are strictly positive,<sup>16</sup> then

$$v\theta\phi\hat{f}_2 > \hat{F}_2 > \frac{\phi}{-v(1-\theta)(\partial\phi/\partial\hat{c}_1)}, \quad (34)$$

which contradicts the requirement of  $\Delta > 0$ .

The overall effect of  $\theta$  on  $\hat{E}$  is

$$\frac{d\hat{E}}{d\theta} = (1 - \hat{F}_2)\hat{f}_1\frac{d\hat{c}_1}{d\theta} + (1 - \hat{F}_1)\hat{f}_2\frac{d\hat{c}_2}{d\theta} = (1 - \hat{F}_1)(1 - \hat{F}_2) \left( \frac{\hat{f}_1}{1 - \hat{F}_1} \frac{d\hat{c}_1}{d\theta} + \frac{\hat{f}_2}{1 - \hat{F}_2} \frac{d\hat{c}_2}{d\theta} \right). \quad (35)$$

The comparative static results with respect to  $\alpha$  are

$$\frac{d\hat{c}_1}{d\alpha} = \frac{-(1-\theta)v}{\Delta}v\theta\hat{f}_2\frac{\partial\phi}{\partial\alpha} < 0 \text{ and } \frac{d\hat{c}_2}{d\alpha} = \frac{(1-\theta)v}{\Delta}\frac{\partial\phi}{\partial\alpha} > 0. \quad (36)$$

The impact on the overall search performance is

$$\begin{aligned} \frac{d\hat{E}}{d\alpha} &= (1 - \hat{F}_1)(1 - \hat{F}_2) \left( \frac{\hat{f}_1}{1 - \hat{F}_1} \frac{d\hat{c}_1}{d\alpha} + \frac{\hat{f}_2}{1 - \hat{F}_2} \frac{d\hat{c}_2}{d\alpha} \right) \\ &= (1 - \hat{F}_1)(1 - \hat{F}_2) \frac{(1-\theta)v}{\Delta} \frac{\partial\phi}{\partial\alpha} \left( \frac{\hat{f}_2}{1 - \hat{F}_2} - \frac{\hat{f}_1}{1 - \hat{F}_1} \hat{f}_2\theta v \right). \end{aligned} \quad (37)$$

Under the DPSM,  $\theta = 0$ ,  $dE^*/d\alpha > 0$  for  $\partial\phi/\partial\alpha > 0$ . When  $\theta > 0$ , the sign of  $d\hat{E}/d\alpha$  depends on

$$\frac{\hat{f}_2}{1 - \hat{F}_2} - \frac{\hat{f}_1}{1 - \hat{F}_1} \hat{f}_2\theta v. \quad (38)$$

Suppose that  $c_1$  and  $c_2$  are distributed uniformly over  $[0, \gamma_1 v]$  and  $[0, \gamma_2 v]$ , respectively. In this case, given that  $\hat{c}_1 = v(1 - \hat{F}_2\theta)$  and  $\hat{c}_2 = v\phi(1 - \theta)$ ,

$$\frac{\hat{f}_2}{1 - \hat{F}_2} = \frac{1/(\gamma_2 v)}{1 - [\hat{c}_2/(\gamma_2 v)]} = \frac{1}{v[\gamma_2 - \phi(1 - \theta)]}, \quad \frac{\hat{f}_1}{1 - \hat{F}_1} = \frac{1}{v[\gamma_1 - 1 + \hat{F}_2\theta]}, \quad (39)$$

and so

$$\frac{\hat{f}_2}{1 - \hat{F}_2} - \frac{\hat{f}_1}{1 - \hat{F}_1} \hat{f}_2\theta v = \frac{1}{v} \left[ \frac{1}{\gamma_2 - (1 - \theta)\phi} - \frac{\theta}{\gamma_2(\gamma_1 - 1 + \hat{F}_2\theta)} \right]. \quad (40)$$

<sup>16</sup>This excludes the case where  $\alpha = 1$  and so  $\partial\phi/\partial\hat{c}_1 = 0$ .

The sign of  $d\hat{E}/d\alpha$  at  $\theta > 0$  is determined by

$$\begin{aligned} \gamma_2(\gamma_1 - 1 + \hat{F}_2\theta) - \theta[\gamma_2 - (1 - \theta)\phi] &= \gamma_2[\gamma_1 - (1 + \theta)] + \gamma_2\theta\frac{\phi(1 - \theta)v}{\gamma_2v} + \phi\theta(1 - \theta) \\ &= \gamma_2[\gamma_1 - (1 - \theta)] + 2\phi\theta(1 - \theta) \leq \gamma_2[\gamma_1 - (1 + \theta)] + \frac{1}{2}, \end{aligned} \quad (41)$$

for  $\phi \leq 1$  and  $\theta(1 - \theta) \leq 1/4$ . Therefore, given any  $\theta > 0$ ,  $d\hat{E}/d\alpha < 0$  for  $\gamma_1 < 1 + \theta$  and  $\gamma_2$  large enough. Q.E.D.

□ **Proposition 3**

*Proof.* When all three cost components have uniform distributions, but different supports, the objective function is  $F_0(\hat{U}_1)\alpha\hat{E} = [\alpha/(\gamma_0v)]\hat{U}_1\hat{E}$ . Finding the analytical solutions of  $\hat{U}_1$  and  $\hat{E}$ , the relevant part of the objective function is

$$\hat{U}_1\hat{E} = \frac{v}{2\gamma_1^2} [1 + 2\theta\hat{F}_2(\gamma_1 - 1) + \theta^2\hat{F}_2^2] [1 + (\gamma_1 - 1)\hat{F}_2 - \theta\hat{F}_2(1 - \hat{F}_2)], \quad (42)$$

where  $\hat{F}_2 = \hat{c}_2/(\gamma_2v) = \phi(1 - \theta)/\gamma_2$ . Ignoring  $v/(2\gamma_1^2)$ , the objective function is proportional to

$$\begin{aligned} 1 + (\gamma_1 - 1)\hat{F}_2 + \theta\hat{F}_2 \left\{ [1 + (\gamma_1 - 1)\hat{F}_2][2(\gamma_1 - 1) + \theta\hat{F}_2] - \right. \\ \left. (1 - \hat{F}_2)[1 + 2(\gamma_1 - 1)\theta\hat{F}_2] - \theta^2\hat{F}_2^2(1 - \hat{F}_2) \right\}. \end{aligned} \quad (43)$$

The DPSM is optimal if the whole term is decreasing in  $\theta$ , for all  $\theta > 0$ . According to the comparative static results in Proposition 1, under uniform distribution,

$$\frac{d\hat{c}_2}{d\theta} = -\frac{v}{\Delta} \left[ \phi + (1 - \theta)v\hat{F}_2\frac{\partial\phi}{\partial\hat{c}_1} \right] = -\phi\frac{v}{\Delta} \left[ 1 + \frac{v}{\gamma_2}(1 - \theta)^2\frac{\partial\phi}{\partial\hat{c}_1} \right], \quad (44)$$

which is negative when  $\gamma_2$  large enough, for  $|\partial\phi/\partial\hat{c}_1| \leq \hat{f}_1/(1 - \alpha) < \infty$  as long as  $\alpha < 1$ . (If  $\alpha = 1$ , then  $\phi = 1$ , a constant.) By  $\hat{f}_1 = 1/(\gamma_1v)$ ,

$$1 + \frac{v}{\gamma_2}(1 - \theta)^2\frac{\partial\phi}{\partial\theta} \geq 1 - \frac{v}{\gamma_2} \frac{(1 - \theta)^2}{(1 - \alpha)\gamma_1v}. \quad (45)$$

When  $\gamma_2$  is large enough such that  $\gamma_2 > 1/[(1 - \alpha)\gamma_1] \geq (1 - \theta)^2/[(1 - \alpha)\gamma_1]$ , an increase in  $\theta$  will reduce  $\hat{c}_2$  and so  $(\gamma_1 - 1)\hat{F}_2$ .

Consider the whole term associated with  $\theta\hat{F}_2$ . It is negative for all  $\theta$  as long as both  $\gamma_1 - 1$  and  $\hat{F}_2$  are small enough. For instance, if  $\gamma_1 - 1$  is close to zero, it becomes  $\theta\hat{F}_2 - (1 - \hat{F}_2) - \theta^2\hat{F}_2^2(1 - \hat{F}_2) < 2\hat{F}_2 - 1 - \theta^2\hat{F}_2^2(1 - \hat{F}_2)$ , by  $\theta \leq \bar{\theta} < 1$ . When  $\gamma_2$  is large

enough such that  $\hat{F}_2 \leq v/(\gamma_2 v) \leq 1/2$ , it is strictly negative. Or, if  $\gamma_1 - 1 = 1/4$ , then, since  $\theta \leq \bar{\theta} < 1$ ,

$$\begin{aligned} & [1 + (\gamma_1 - 1)\hat{F}_2][2(\gamma_1 - 1) + \theta\hat{F}_2] - (1 - \hat{F}_2)[1 + 2(\gamma_1 - 1)\theta\hat{F}_2] \\ &= -\frac{1}{2} + \frac{3\theta}{4}\hat{F}_2^2 + \left(\frac{9}{8} + \frac{\theta}{2}\right)\hat{F}_2 < -\frac{1}{2} + \frac{3}{4}\hat{F}_2^2 + \frac{13}{8}\hat{F}_2, \end{aligned} \quad (46)$$

which is strictly negative if  $\gamma_2$  is large enough such that  $\hat{F}_2$  is smaller than, say,  $1/8$ .  
Q.E.D.

#### □ Proposition 4

*Proof.* The impact of the policy  $\theta$  on the total surplus is

$$\frac{dS}{d\theta} = F_0(\hat{U}_1) \frac{d\hat{U}_1}{d\theta} + (1 - \alpha\hat{F}_1)f_0(\hat{U}_1)\hat{U}_2 \frac{d\hat{U}_1}{d\theta} - F_0(\hat{U}_1) \left[ \alpha\hat{f}_1\hat{U}_2 \frac{d\hat{c}_1}{d\theta} - (1 - \alpha\hat{F}_1) \frac{d\hat{U}_2}{d\theta} \right]. \quad (47)$$

By the envelope theorem, the direct effect of  $\theta$  on an inventor's choice variable can be ignored:

$$\frac{d\hat{U}_1}{d\theta} = \frac{\partial\hat{U}_1}{\partial\hat{c}_2} \frac{d\hat{c}_2}{d\theta} + \frac{\partial\hat{U}_1}{\partial\theta} = (1 - \hat{F}_1)v \left[ \hat{F}_2 + \theta\hat{f}_2 \frac{d\hat{c}_2}{d\theta} \right], \quad (48)$$

$$\frac{d\hat{U}_2}{d\theta} = \frac{\partial\hat{U}_2}{\partial\hat{c}_1} \frac{d\hat{c}_1}{d\theta} + \frac{\partial\hat{U}_2}{\partial\theta} = \hat{F}_2v \left[ (1 - \theta) \frac{\partial\phi}{\partial\hat{c}_1} \frac{\partial\hat{c}_1}{\partial\theta} - \phi \right]. \quad (49)$$

At  $\theta = 0$ ,  $d\hat{U}_1/d\theta = (1 - \hat{F}_1)\hat{F}_2v > 0$ . By the comparative static results in the proof of Proposition 1,  $d\hat{c}_1/d\theta = -\hat{F}_2v < 0$ . When  $\theta = 0$ , the only negative term in  $dS/d\theta$  is the one associated with  $\phi$  in  $d\hat{U}_2/d\theta$ , i.e.,

$$F_0(\hat{U}_1)(1 - \alpha\hat{F}_1)(-\hat{F}_2v\phi) = -F_0(\hat{U}_1)(1 - \hat{F}_1)\hat{F}_2v, \quad (50)$$

which is exactly canceled by the first term in  $dS/d\theta$ , for

$$F_0(\hat{U}_1) \frac{d\hat{U}_1}{d\theta} \Big|_{\theta=0} = F_0(\hat{U}_1)(1 - \hat{F}_1)\hat{F}_2v. \quad (51)$$

Therefore,  $dS/d\theta > 0$  at  $\theta = 0$ .
