Abstract

We quantify the impact of bank market power on the pass-through of monetary policy to borrowers. To this end, we estimate a dynamic banking model in which monetary tightening increases banks’ funding costs. Given their market power, banks optimally choose how much of a rate increase to pass on to borrowers. In the model, banks are subject to capital and reserve regulations, which also influence the degree of pass-through. Compared with the conventional regulation-based channels, we find that in the two most recent decades, bank market power explains a significant portion of monetary transmission. The quantitative effect is comparable in magnitude to the bank capital channel. In addition, the market power channel interacts with the bank capital channel, and this interaction can reverse the effect of monetary policy when the Federal Funds rate is low.

1. Introduction

We examine the quantitative importance of bank market power as a transmission mechanism for monetary policy. This question is interesting because traditional theories and analysis of monetary policy transmission via bank lending focus on regulatory constraints such as reserve or capital requirements (e.g. Bernanke and Blinder 1988; Kashyap and Stein 1995). Indeed, the banking industry is often assumed to be perfectly competitive, leaving only these regulatory frictions as a channel through which monetary policy affects loan supply. However, recent research suggests that the industrial organization of the banking sector may also play a role in the transmission of monetary policy (Drechsler, Savov, and Schnabl 2017; Scharfstein and Sunderam 2016). This newer literature, while important, has been qualitative in nature, leaving open the question of the relative importance of traditional versus market-power channels for the transmission of monetary policy.

Our paper tries to fill this void by constructing and estimating a dynamic banking model with three important frictions: regulatory constraints, financial frictions, and imperfect competition. The estimation allows data to discipline the model parameters and thus expose the relative magnitude of these three frictions. We find that regulatory frictions restricting bank capital and bank market power both play an important role in monetary policy transmission, while reserve requirements are unimportant. In terms of magnitude, the effect of bank market power is comparable in magnitude to that of bank capital. We also find an interesting interaction between different monetary policy transmission channels. Specifically, we show that bank capital regulation interacts with market power and reverses the sign of monetary policy when the Federal Funds rate is very low. We estimate that when the Federal Funds rate is below 2.27%, further cuts in the policy rates can be contractionary. Moreover, we find external validation of this reversal rate by showing in a simple regression framework that the relation between bank capital and interest rates switches sign at approximately this interest rate.
An understanding of the intuition behind these results requires a deeper description of the model. In the economy, banks act as intermediaries between borrowers and depositors. The lending decision is dynamic because deposits are short-term, while loans are long-term. Monetary tightening increases banks’ funding costs in the deposit market. Because they are not price takers in the deposit and loan market, banks choose how much of a rate increase to pass on to borrowers. The degree of pass-through is influenced by the tightness of regulatory constraints, the degree of financial frictions, and the intensity of competition.

These frictions in our model map into three monetary policy transmission channels emphasized in the literature, the first of which is the bank reserve channel whereby high interest rates increase the opportunity cost of holding reserves (Bernanke and Blinder 1988; Kashyap and Stein 1995) and thus contract deposit creation. The second is the bank capital channel whereby high interest rates lower bank capital and, consequently, the capacity to lend (Bolton and Freixas 2000; Van den Heuvel 2002; Brunnermeier and Sannikov 2016). The third is the market power channel whereby bank concentration affects the transmission of monetary policy (Drechsler, Savov, and Schnabl 2017; Scharfstein and Sunderam 2016). Intuitively, after a rate increase, cash becomes less attractive to households relative to deposits. Monopolistically competitive banks can exploit this extra demand by charging higher spreads on deposits. In equilibrium, total deposits fall because households substitute risk-free bonds for deposits. Because banks then need to fund marginal lending in the more expensive debt market, lending contracts.

To gauge the quantitative importance of these transmission channels, we estimate the model using a panel of U.S. commercial banks. Our estimation combines methods used in the industrial organization literature (Berry, Levinsohn, and Pakes 1995; Nevo 2001) with those used in the corporate finance literature (Hennessy and Whited 2005; Bazdresch, Kahn, and Whited 2018). As a first step, we use the demand estimation techniques from industrial organization to obtain the elasticities of substitution in the deposit and loan markets. We then plug these estimates into our model, and use simulated method of moments to obtain
estimates of parameters that quantify financial frictions and operating costs. The sequential use of these two techniques is a methodological advance that allows us to consider a rich equilibrium model that would otherwise be intractable to estimate.

To obtain our results on the relative importance of each transmission channel, we then use these parameter estimates to simulate counterfactual experiments in which we subtract each channel from the model one at a time. These counterfactuals also produce our interesting result that rate cuts can be contractionary when rates are already low. Low interest rates depress bank profits by reducing bank market power in the deposit market, as cash becomes less unattractive to households. Lower profits then tighten the capital constraint and result in less lending. This result sheds light on the sluggish bank lending growth post crisis, as the ultra-low rate policy can unintentionally reduce bank profitability, and consequently constrain banks’ capacity to lend. Overall, our results suggest that Federal Reserve actions can have complicated effects on bank lending depending on the level of policy rates, the amount of bank capital, and the industrial organization of the banking sector.

Our paper contributes to the literature studying the role of banks in transmitting monetary policy. It is the first to estimate a structural dynamic banking model to quantify various transmission channels.\(^1\) Prior to our work, little has been known about the relative importance of different transmission channels, as this type of quantitative exercise is difficult to undertake using reduced form methods.

Second, prior literature usually studies each transmission channel separately, but little is known about the interactions between different channels. A contribution of this paper is to provide a unified framework to study these interactions. For example, Drechsler, Savov, and Schnabl (2017) and Scharfstein and Sunderam (2016) study the market power in the deposit market and loan market separately. We show that the relative importance of the two markets depends on the level of the Federal Funds rate. The deposit market is more important when the Federal Funds rate is low while the loan market becomes more important when

\(^1\)Xiao (2018) also uses a structural approach, but the main focus is on shadow banks.
the Federal Funds rate is high. Brunnermeier and Koby (2016) put forth the theoretical possibility that monetary policy can switch sign at a certain threshold referred to as a “reversal rate.” Our paper provides an empirical estimation of this threshold.

Third, our paper is related to the literature on external financial frictions. Largely focused on industrial firms, this literature shows that financial frictions significantly affect corporate policies such as investment, cash holding, and dividend payout. We show that banks also face significant financial frictions despite their regular participation in the capital markets. This last result supports the arguments in Kashyap and Stein (1995) that banks’ high external financing costs can influence the quantity of bank lending.

2. Data

Our main data set is the Consolidated Reports of Condition and Income, generally referred to as the Call Reports. This data set provides quarterly bank-level balance sheet information for U.S. commercial banks, including deposit and loan amounts, interest income and expense, loan maturities, salary expenses, and fixed-asset expenses. We merge the Call Reports with the FDIC Summary of Deposits, which provides branch-level information for each bank since 1994 with annual frequency. We follow Egan, Hortacsu, and Matvos (2017) by excluding banks with fewer than ten domestic branch locations. This filter eliminates foreign banks with very few U.S. branches and tiny local banks.

Table 1 provides the summary statistics of the sample for the BLP demand estimation. The sample period for the demand estimation is from 1994 to 2017. In the baseline estimation, we take the entire United States as a unified market to compute market shares of each bank in the deposit and loan market. The total size of the deposit market is defined as the sum of deposits, cash, and bonds held by all the U.S. households. The total size of the loan market is defined as the sum of bank loans and corporate bonds borrowed by the U.S.

---

2The result is robust when we include risky assets as an option.
firms. Following the literature, we impute deposit (loan) rates by dividing interest expenses (income) over the total amount of deposits (loans). We include two non-rate characteristics in the demand estimation: number of branches and number of employees per branch. Lastly, following the literature, we use expenses of the fixed assets and salary as supply shifters (Ho and Ishii 2011). Expenses of the fixed assets include all non-interest expenses related to the use of premises, equipment, furniture, and fixtures. We scale expenses of the fixed assets and salary using total assets.

In addition to bank balance sheet data, we retrieve stock returns of public listed banks from CRSP to examine the price response to monetary news. We link the stock returns to bank concentration measure using the link table provided by the Federal Reserve Bank of New York.\(^3\) We obtain bank industry stock returns from Kenneth French’s website. We collect the Federal Open Market Committee meeting dates from the FOMC Meeting calendar.\(^4\) The sample period for the stock return data is from 1994 to 2017. Finally, we obtain the following time series from FRED (Federal Reserve Economic Data): NBER recession dates, the effective Federal Funds rate, the two-year and five-year Treasury yields, the aggregate amount of corporate bonds issued by U.S. firms, and the aggregate amount of cash, Treasury bonds, and money-market mutual funds held by households.

3. Stylized Facts

We start with some time series facts regarding bank lending. Figure 1 plots average U.S. bank loan-to-deposit ratios following the five recessions from 1973 to 2017. The loan-to-deposit ratio usually falls when the recession starts as both loan demand and supply falls. In the first three recessions during this period, the loan-to-deposit ratio recovered three to four years after the start of the recession. However, the recoveries after the 2001 and 2008 recessions are notably slower. The loan-to-deposit ratio took six to seven years to recover

\(^3\)See: https://www.newyorkfed.org/research/banking_research/datasets.html
\(^4\)See: https://www.federalreserve.gov/monetarypolicy/fomccalendars.htm
after the 2001 recession, and this ratio still has not yet recovered 10 years after the 2008 recession. This sluggishness is surprising given that both recessions ended within two years.

Although many factors such as regulatory changes could be behind the lengthy recovery in bank lending, one feature that these two episodes share is protracted periods in which the Federal Reserve lowered short-term interest rates to near zero. As such, loose monetary policy is a possible culprit. However, conventional wisdom suggests that this possibility is unlikely, as high interest rates should have a negative impact on bank capital. Because bank loans are long-term and deposits are short-term, an increase in interest rates reduces the value of assets more than the value of liabilities, so bank equity falls. At the same time, high interest rates reduce loan demand, also depressing bank equity. This negative relation between interest rates and bank equity is central to the bank capital channel of monetary policy, as lower bank equity implies a tighter capital constraint, which in turn leads to less lending.5

To understand this issue, we examine the relation between bank equity returns and interest rates. Interestingly, when we examine the response of bank stock returns to shocks to monetary policy, we find that the negative relation between interest rates and bank equity reverses sign if interest rates are close to zero. Specifically, we regress U.S. bank stock returns on the change in two-year Treasury yield on Federal Open Market Committee (FOMC) meeting days. We focus on FOMC days following Hanson and Stein (2015), who measure changes in monetary policy with daily changes in the two-year Treasury yield surrounding FOMC meetings. The advantage of examining the two-year Treasury yield instead of the Federal Funds rate is that the former captures the effects of “forward guidance” in the FOMC announcement, which has become increasingly important in recent years (Hanson and Stein 2015).6 The identifying assumption is that unexpected changes in interest rates in a one-

---

5One may worry that our finding is mainly driven by an increase in the denominator, the deposits. To address this concern, in the Online Appendix, we plot the amount of loans following the onset of each recession. We further separate banks into two groups according to their capital ratios. We find that banks with below-median capital ratios experience much lower loan growth following the recession. The gap between poorly-capitalized and well-capitalized banks is particularly large in 2001 and 2008 recession.

6We also use 1-year Treasury yield and the results are robust.
day window surrounding scheduled Federal Reserve announcements arise from news about monetary policy.

Table 2 reports the regression estimates, where our sample period runs from 1994 to 2017. We exclude the burst of dot-com bubble (2000-2001) and the subprime financial crisis (2007-2009) because in these crisis time monetary policy may be strongly influenced by the stock market rather than by inflation and economic growth (Cieslak and Vissing-Jorgensen 2017). We split the sample into a high Federal Funds rate regime and a low Federal Funds rate regime. While we use 2% as the cutoff, we show below that 2% is the threshold at which bank deposits face intense competition from cash. In column 1, we show that when the Federal Funds rate is above 2%, an increase in the two-year Treasury yield is associated with negative significant returns for bank stocks. This result is consistent with the conventional wisdom that news of monetary tightening reduces bank capital due to their maturity mismatch.

In contrast, in Column 2, we show that when the Federal Funds rate is below 2%, an increase in the two-year Treasury yield is associated with positive significant returns for bank stocks. In other words, the market expects that an increase in the interest rates leads to an increase in bank capital. This low-interest-rate result stands in contrast to the conventional wisdom that monetary tightening reduces bank capital. This result is not driven by a steepening of the term structure, as we control for the change in the five-year term spread over two-year Treasury, where we pick the five-year spread to match the average maturity of bank loans in our sample, which is five years. As shown in Figure 2, the contrast between the results in Columns 1 and 2 can be seen in a simple scatter plot of bank industry excess returns against the change in the two-year Treasury yield. In summary, we find that monetary policy has a nonmonotonic effect on bank capital. When the Federal Funds rate is high, the relation between the Federal Funds rate and bank capital seems be to negative, but when the Federal Funds rate is low, this relation becomes negative. As far as we know, 

\footnote{In the Online Appendix, we examine all the 49 industry returns. We find that the banking industry is the only industry that switch from a negative interest sensitivity to positive interest sensitivity in the low interest environment.}
this paper is the first to document this empirical relation.

To delve into the mechanism behind this basic result, in Columns 3 and 4 of Table 2, we interact the change in the interest rate with a measure of bank market power, the Herfindahl-Hirschman index of the local deposit market in which the bank operates.\(^8\) We find that when the Federal Funds rate is below 2%, banks with greater market power in the deposit market experienced larger positive returns.

This evidence lends credence to the hypothesis that loose monetary policy contributed to the slow recovery in bank lending after the last two recessions. If bank lending-capacity depends on the amount of bank capital, a direct implication of the above finding is that an ultra-low rate monetary policy could be contractionary for bank lending.

4. Model

We consider an infinite-horizon, equilibrium model with three sectors: households, firms, and banks. Banks act as intermediaries between households and firms by taking short-term deposits from households and providing long-term loans to firms. We model the households simply as solving straightforward static discrete choice problems. The richness of the model lies in the banking sector, as a variety of frictions imply that monetary policy affects the amount of intermediation that banks provide. These frictions are important because in a frictionless world where bank loans and bonds are perfect substitutes, bond market interest rates summarize monetary policy and banks are simply pass-through entities. However, if bank loans and bonds are imperfect substitutes (Bernanke and Blinder 1988), the supply of bank loans matters for monetary policy in its own right.

Since Bernanke and Blinder (1988), researchers have identified many frictions that affect monetary transmission through banks. Our model incorporates the following prominent

---

\(^8\)A local deposit market is defined as a Metropolitan Statistical Area (MSAs) If a bank operates in several MSAs, the bank-level HHI is the weighted average of local HHIs, weighted by the deposits of the bank in the local market.
channels featured in the literature. First, access to non-deposit external financing is more costly than taking deposits. This friction implies that shocks to the quantity of deposits are transmitted to the supply of bank loans, as banks cannot costlessly replace deposits with non-reservable borrowing. Second, competition in the deposit and loan markets is imperfect. With market power, banks strategically choose the deposit rate and loan rate to maximize their profits. This profit maximizing behavior, in turn, determines how monetary policy transmits through the banking system. Third, banks are subject to reserve regulation and capital regulation. Reserve regulation links the opportunity cost of taking deposits to the prevailing Federal Funds. Capital regulation incentivizes banks optimize their loan supply intertemporally with an eye to preserving excess equity capital as a buffer against future capital inadequacy.

4.1 Households

At each time $t$, the economy contains $W_t$ households, each of which is endowed with one dollar. Hereafter, we the time subscript for convenience, so aggregate household wealth is then $W$. Households choose among the following investment options for their endowments: cash, corporate bonds, and bank deposits, where the deposits of each individual bank constitute a differentiated product. If index each option by $j$, households’ choice set is given by $\mathcal{A}^d = \{0, 1, \ldots, J, J + 1\}$, with option 0 representing cash, option $J + 1$ representing short-term bonds, and options $1, \ldots, J$ representing deposits in each bank. We further assume that each depositor can choose only one option.

Each option is characterized by a yield, $r^d_j$, and a quality value, $q^d_j$. The yield on cash is 0, and the yield on bonds is the Federal Funds rate, $f$. $q^d_j$ captures the convenience of option $j$ to a depositor. For a bank, $q^d_j$ can reflect the bank’s number of branches or the number of employees per branch. For the other options, $q^d_j$ can capture the ease with which the household can use the option as a medium of transaction. We assume $q^d_j$ varies only with households and not with banks, where we allow households to belong to a finite set
of types, indexed by \(i \in 1, 2, \ldots, I\). A household’s utility from choosing option \(j\) is given by \(u_{i,j} = \alpha^d_i r_j^d + q_j^d + \epsilon_{i,j}^d\), \(\alpha^d_i\) is the yield sensitivity and \(\beta^d_i\) is the sensitivity to the quality value. \(\epsilon_{i,j}^d\) is a relationship specific shock for the choice of option \(j\) by household \(i\). We assume \(\epsilon_{i,j}^d\) follows a generalized extreme value distribution with a cumulative distribution function given by \(F(\epsilon) = \exp(-\exp(-\epsilon))\). This distributional assumption is standard in the structural industrial organization literature and allows for a closed-form solution for the consumer’s probability of making each choice.

The decision of each household is then to choose the best option to maximize its utility:

\[
\max_{j \in A^d} u_{i,j} = \alpha^d_i r_j^d + q_j^d + \epsilon_{i,j}^d.
\] (1)

The solution to (1) implies that the demand for the deposits of bank \(j\) is given by the following formula:

\[
s_j^d (r_j^d) = \sum_{i=1}^{I} \mu_i^d \frac{\exp \left( \alpha^d_i r_j^d + q_j^d \right)}{\sum_{m \in A^d} \exp \left( \alpha^d_i r_m^d + q_m^d \right)},
\] (2)

where \(\mu_i^d\) is the fraction of total wealth \((W)\) held by households of type \(i\). The quantity of deposits is then given by the market share multiplied by total wealth, \(D_j = s_j^d W\).

**Firms**

There are \(K\) firms, each of which wants to borrow one dollar, so aggregate borrowing demand is \(K\). Firms can borrow by issuing long-term bonds or taking out bank loans. We assume that each individual bank is a differentiated lender, where this assumption is motivated by such factors as geographic location or industry expertise. Letting each option be indexed by \(j\), the firms’ choice set is given by \(A^l = \{0, 1, \ldots, J, J + 1\}\), where option 0 represents bonds, option 1, \(\ldots\), \(J\) represents loans from each bank, and option \(J + 1\) is the option not to borrow at all. Each option is characterized by a lending rate, \(r_j^l\), and a vector of product characteristics, \(x_j^l\). As above, these characteristics can include the number of branches or employees per branch.
For tractability, we assume that both bonds and bank loans have the following repayment schedule. Each period the firm has to pay back a fraction $\mu$ of its outstanding debt, where $\mu$ includes both interest accrued over the last period, as well as some amortized principal. For instance, if the firm borrow a nominal value of one dollar, the repayment stream, starting in the next period, is $\mu, (1 - \mu)\mu, (1 - \mu)^2\mu, \ldots$. Accordingly, all firm debt has an average maturity of $\frac{1}{\mu}$ periods. This construction saves us from having to track the entire age distribution of a bank’s loan portfolio. Thus, a sufficient statistic for the future repayment schedule is just the total amount outstanding.

We assume that the interest rate on the long-term bond ($\bar{f}_t$) is set according to:

$$
\sum_{n=0}^{\infty} \frac{\mu(1 - \mu)^n}{(1 + \bar{f}_t)^{n+1}} = \frac{\mu}{1 + \bar{f}_t} + \mathbb{E}_t \left[ \sum_{n=1}^{\infty} \frac{\mu(1 - \mu)^n}{\prod_{m=0}^{n} (1 + f_{t+m})} \right]
$$

Put differently, $\bar{f}_t$ is the fixed rate that produces the bond’s fair present value when used to discount the bond’s cash flows. Fair present value, in turn, is simply this expected value of this cash flow stream discounted at the (non-constant) Federal Funds rate, $f_t$. Each option is characterized by a rate, $r^j_l$, and a quality value, $q^j_l$, which reflects the effort a firm has to exert to borrow via option $j$. In case of a bank loan, $q^j_l$ can include the number of branches or the number of employees per branch. In the case of the corporate bond, $q^j_l$ can capture the cost of hiring an underwriter. We assume $q^j_l$ varies only with firms and not with banks, where, as in the case of the households, we allow firms to belong to a finite set of types, indexed by $i \in 1, 2, \ldots, I$.

The profit for firm $i$ from choosing option $j$ is given by $\pi_{i,j} = \alpha^j_i r^j_l + q^j_l + \epsilon^j_{i,j}$, where $\alpha^j_i$ is the yield sensitivity, and $\epsilon^j_{i,j}$ is an idiosyncratic relationship shock when a firm $i$ borrows from bank $j$. We assume $\epsilon^j_{i,j}$ follows a generalized extreme value distribution with a cumulative distribution function $F(\epsilon) = \exp (-\exp (-\epsilon))$. Each firm’s decision is to choose the best

---

9We have recycled the notation $i$ to index firms and $j$ to index firm’s borrowing options.
option to maximize its profit, as follows:

$$\max_{j \in A} \pi_{i,j} = \alpha_i^l r_j^l + q_j^l + \epsilon_{i,j}^l. \tag{4}$$

The solution to (4) implies that the demand for the loans of bank $j$ is given by:

$$s_j^l(r_j^l) = \frac{\sum_{i=1}^l \mu_i^l \exp(\alpha_i^l r_j^l + q_j^l)}{\sum_{m \in A} \exp(\alpha_m^l r_m^l + q_m^l)}, \tag{5}$$

where $\mu_i^l$ is the fraction of type $i$ firms. Loan quantity is given by the market share multiplied by the total market size, $B_j = s_j^l K$.

4.2 The Banking Sector

Given the Federal Funds rate, $f_t$, each bank simultaneously sets its deposit rate, $r_{j,t}^d$, and its loan rate $r_{j,t}^l$, thereby implicitly choosing the quantities of deposits to take from households and credit to extend to firms. For example, given each bank $j$’s choice of $r_{j,t}^d$, households solve their utility maximization problem described above, which yields the quantity of deposits supplied to bank $i$, $D_i(r_{i,t}^d)$. Similarly, given each bank $j$’s choice of $r_{j,t}^l$, firms solve their profit maximization problem, which yields the quantity of loans borrowed from bank $j$, $B_j(r_{j,t}^l)$.

This lending activity involves a maturity transformation. Let $L_{i,t}$ denote the amount of loans that the bank currently holds. In each period, as in the case of bonds, a fraction, $\mu$, of a bank’s outstanding loans matures, with principle plus interest payments equal to $\mu \times L_{i,t}$. This assumption about long-term loans captures a traditional maturity transformation role for banks, in which they convert one-period deposits into long-term bank loans with maturity $\frac{1}{\mu}$. As noted above, banks can also issue new loans with an annualized interest rate of $r_{j,t}^l$. The new loans, once issued, have the same maturity structure as the existing ones, with a fraction $\mu B(r_{j,t}^l)$ becoming due each year.

We denote by $P(B_{j,t}, r_{j,t}^l)$ the amount bank $j$ extends to firms. Fair pricing implies that
this quantity is simply the discounted the payment stream at the constant loan rate $r_{j,t}$:

$$P(B_{j,t}, r_{j,t}) = \sum_{m=0}^{\infty} \frac{(1 - \mu)^m \mu B_{j,t}}{(1 + r_{j,t})^{m+1}} = \frac{\mu}{r_{j,t} + \mu} B_{j,t}$$ (6)

Notice that if the loan rate $r_{j,t}$ is set to 0, then equation (6) simplifies to $P(B_{i,t}, r_{i,t}) = B_{i,t}$, showing that the amount the bank gives to firms at the present period simply equals the sum of all future payments. If $\mu$ is set to one, then debt has a maturity of one year, and the interest income from lending is $B_{j,t} - P_{j,t} = \frac{r_{j,t}}{1 + r_{j,t}} B_{j,t} \approx r_{j,t} B_{j,t}$.

We assume that a random fraction of loans falls delinquent in each period. As such, a bank’s outstanding loans evolve according to:

$$L_{j,t+1} = (1 - \mu)(L_{j,t} + B_{j,t}) - \delta_t L_{j,t},$$ (7)

where $\delta_t \in [0, 1]$ is the random fraction of loans that become due but that the borrower fails to pay in period $t$. Although we assume that delinquent payments are written off by the bank, with charge-offs equal to $A_t \equiv \mu L_t \times \delta_t$, defaulting on a payment in one period does not exonerate the borrower from payments in future periods.

We summarize the rest of the bank’s activities in the balance sheet given in Table 3, where we suppress the subscript for bank identity, $j$, for convenience. Here, we see that the banks assets consist of existing plus new loans, reserves, and holdings of government securities. Its liabilities consist of deposits, borrowing not subject to reserve requirements. The difference is then bank equity. We now go through these items in detail.

In each period, the bank can rely on deposits or internal retained earnings to finance its new loans, $B_t$. When the supply of funds falls short of loan demand, the bank can also borrow via non-reservable securities, $N_t$. A typical example of non-reservable borrowing is large denomination CDs. As argued by Kashyap and Stein (1995), because non-reservable borrowing is not insured by FDIC deposit insurance, purchasers of this debt must concern themselves with the default risk of the issuing bank. These considerations make the marginal
cost of non-reservable borrowing an increasing function of the amount raised, and motivate our next assumption, which is that non-reservable borrowing incurs a quadratic financing cost beyond the prevailing Federal Funds rate, as follows:

$$\Phi^N(N_t) = \phi^N N_t^2.$$  (8)

Banks also incur operating costs, such as rents and wages. We assume that costs are linear in the amount of deposits:

$$\Phi^d(D_t) = \phi^d D_t.$$  (9)

Similarly, we also assume that lending activity itself incurs separate costs, such as labor input necessary to screen loans or maintain client relationships. Again, we assume a linear functional form as follows:

$$\Phi^l(B_t) = \phi^l B_t.$$  (10)

If the total supply of funds exceeds the demand from the lending market, the bank can invest in government securities, $G_t$, where the return is the Federal Funds rate, $f_t$. The bank’s holdings of loans, government securities, deposits, reserves, and non-reservable borrowing must satisfy the standard condition that assets equal liabilities plus equity:

$$L_t + P(B_t, r_l) + R_t + G_t = D_t + N_t + E_t,$$  (11)

where $R_t$ denotes bank reserves and $E_t$ is the bank’s begin-of-period book equity. $E_t$ itself evolves according to:

$$E_{t+1} = E_t + \Pi_t \times (1 - \tau) - C_t$$  (12)

where $\tau$ denote the linear tax rate, and $\Pi_t$ is the bank’s total operating profit from its deposit taking, security investments, and lending decisions. These profits, in turn, are given by:

$$\Pi_t = B_t - P(B_t, r^l_t) - D_t \times r^d_t + G_t \times f_t - \Phi^l(B_t) - \Phi^d(D_t) - \Phi^N(N_t) - \mu L_t \times \delta_t.$$  (13)
Finally, $C_t$ in equation (12) represents the cash dividends distributed to the bank’s shareholders. We assume that a bank can only increase its inside equity via retained earnings, that is, there is no new equity issuance, so:

$$C_t \geq 0 \quad \forall t. \tag{14}$$

This constraint reflects a bank’s limited liability, which prevents it from obtaining any external equity financing from shareholders. This constraint represents an important friction because in its absence, banks could always raise equity capital to fund any shortfall in the loanable funds market. This activity would disconnect banks’ deposit taking decisions from their lending decisions, so changes in the Federal Funds rate would not have an impact on lending. Equation (14) implies that model cannot capture the equity issuances we see in the data. However, given that banks’ equity issuances are both tiny and rare, we view this drawback of our model as minor.

We now introduce the capital requirement and the reserve requirement:

$$E_{t+1} \geq \kappa \times L_{t+1} \tag{15}$$
$$R_t \geq \theta \times D \tag{16}$$

Equation (15) implies that the bank’s book equity at the beginning of the next period has to be no smaller than a fraction, $\kappa$, of the loans outstanding. Equation (16) is the bank reserve requirement, which says that the bank has to keep $\theta$ of its deposits in a non-interest bearing account with the central bank. Zero interest on reserves implies that the bank has no incentive to hold excess reserve, so equation (16) holds with equality.

To close the model, we assume that the law of motion for the bank loan charge-offs and
the Federal Funds rate is given by:

\[
\begin{bmatrix}
\ln \delta_{t+1} \\
\ln f_{t+1}
\end{bmatrix} = \begin{bmatrix}
\rho_\delta & \rho_\delta f \\
0 & \rho_f
\end{bmatrix} \cdot \begin{bmatrix}
\ln \delta_t \\
\ln f_t
\end{bmatrix} + \begin{bmatrix}
\sigma_\delta & 0 \\
0 & \sigma_f
\end{bmatrix} \cdot \mathcal{N}_2,
\]

(17)

where \(\mathcal{N}_2\) stands for the density function of a standard bi-variant normal distribution.

### 4.3 Bank’s problem and equilibrium

Figure 7 summarizes the sequence of events in a typical time period. The bank enters the period and observes the Federal Funds rate, \(f_t\) and the realization of the default fraction, \(\delta_t\). At that point it takes the corresponding charge-offs. Next, banks interact with households and firms by setting the loan and deposit spreads, receiving the corresponding amount of deposits from households, and extending the corresponding amount of loans to firms. Depending on the extent of these activities, the banks will adjust their reserves, holdings of government securities, and non-reservable borrowing. Finally, at the end of the period, a fraction \(\mu\) of the loans mature, and banks collect profits and distribute dividends to shareholders.

As discussed above, loan and deposit demand depend on the rates put forth by all banks in the economy. Accordingly, each bank, when choosing its own deposit and loan rates \((r^d_t\) and \(r^l_t\)), non-reservable borrowings \((N_t)\), as well as investment in government securities \((G_t)\), rationally takes into account the choices made by other banks in the present as well as in all future periods. We denote by \(\Gamma_t\) the composition of the banking sector, that is, the cross-sectional distribution of bank states. We denote by \(P^\Gamma\) the probability law governing the evolution of \(\Gamma_t\), so:

\[
\Gamma_{t+1} = P^\Gamma(\Gamma_t).
\]

(18)

Every period, after observing the Federal Funds rate \((f_t)\) and the random fraction of defaulted loans \((\delta_t)\), the banks choose the optimal policy to maximize its discounted cash
dividends to shareholders:

\[
V(f_t, A_t, L_t, E_t | \Gamma_t) = \max_{\{\lambda_t^d, \lambda_t^l, G_t, N_t, R_t\}} \left\{ C_t + \frac{1}{1 + \gamma} \mathbb{E} V(f_{t+1}, A_{t+1}, L_{t+1}, E_{t+1} | \Gamma_{t+1}) \right\}
\]  

(19)

\[
s.t. \quad (8), (9), (10), (11), (12), (18),
\]

where \( \gamma \) is the bank’s discount factor.

We define equilibrium in this economy as follows.

**Definition 1** A stationary equilibrium occurs when:

1. All banks solve the problem given by (19), taking as given the other banks’ choices of loan and deposit rates.
2. All households and firms maximize their utilities given the list of rates put forth by banks.
3. Each period, the deposit and loan markets clear.
4. The probability law governing the evolution of the industry, \( P^\Gamma \), is consistent with banks’ optimal choices.

One of the state variables for bank’s problem (\( \Gamma_t \)) is an object whose dimension depends on the number of banks in the economy. This dimensionality poses a challenge for numerically solving the banks’ problem. To simplify the model solution, we follow Krusell and Smith (1998) by considering a low-dimensional approximation of \( \Gamma_t \). Specifically, we postulate that all information about \( \Gamma_t \) relevant to banks’ optimization can be summarized by the contemporaneous Federal Funds rate (\( f_t \)). Accordingly, we define the equilibrium “average” loan and deposit rates \( \bar{r}_t^l(f_t) \) and \( \bar{r}_t^d(f_t) \), respectively, as,

\[
\exp(\alpha d \bar{r}_t^d + \beta d x_t^d + \xi_t^d) \equiv \mathbb{E}\left[\exp(\alpha d r_t^d + \beta d x_t^d + \xi_t^d)\right],
\]

(20)

and

\[
\exp(\alpha l \bar{r}_t^l + \beta l x_t^l + \xi_t^l) \equiv \mathbb{E}\left[\exp(\alpha l r_t^l + \beta l x_t^l + \xi_t^l)\right].
\]

(21)
With a reasonably large number of banks, \( \bar{r}^d_l(f_t) \) and \( \bar{r}^d_t(f_t) \) approximately summarizes the choices of other banks, thereby allowing each bank to derive its deposit and loan demand functions. In solving the model, we ensure that \( \bar{r}^d_l(f_t) \) and \( \bar{r}^d_t(f_t) \) are consistent with equilibrium bank choices by iterating over their values until convergence. As \( \bar{r}^d_l(f_t) \) and \( \bar{r}^d_t(f_t) \) are functions of \( f_t \) only, we drop \( \Gamma_t \) from banks’ value functions in (19).

### 4.4 Monetary policy transmission

In this section, we use a simplified version of the model to illustrate the key transmission mechanisms.

#### 4.4.1. Frictionless benchmark

First, we examine how the economy behaves in a frictionless benchmark model. By frictionless, we are referring to a simplified version of our model with the following five features:

1. the bank has no market power in either the deposit or the loan market, i.e., the demand elasticity is infinite, \( -\frac{D'}{D} \to \infty, \frac{B'}{B} \to \infty \);
2. there are no frictions related to non-reservable borrowing;
3. the bank faces no capital requirement, \( \kappa = 0 \);
4. there is no reserve requirement, \( \theta = 0 \); and
5. there is no maturity transformation.

These features imply that the bank’s problem can be viewed as a static problem.

In this static frictionless model, banks choose deposit rates, \( r^d \), and loan rates, \( r \), to maximize one-period profits

\[
\Pi = \max_{(r^d, r)} r^d B(r^d) - r^d D(r^d) - \phi^d B(r^d) - \phi^d D(r^d) - f(B(r^d) - D(r^d))
\]  

(22)

When deposits fall short of loans, the bank can make up any funding shortfall, \( B - D \), with non-reservable borrowing at a cost equal to the Federal Funds rate, \( f \). There are no additional financing costs associated with non-reservable borrowing. When there are excess deposits, the bank can invest any this surplus, \( D - B \), in government securities and earn the
Federal Funds rate, $f$. In the absence of a balance sheet friction, the bank can optimize its choices for deposit and loan amounts ($B$ and $D$) separately.

The optimal lending rates are given by the Federal Funds rate plus the marginal cost and the markup:

$$ r^l = f + \phi^l + \left( -\frac{B'}{B} \right)^{-1}, $$

and the optimal deposit rates are given by the Federal Funds rate minus the marginal cost and the markup:

$$ r^d = f - \phi^d - \left( \frac{D'}{D} \right)^{-1}. $$

When there is perfect competition among banks, the demand elasticities, $-\frac{B'}{B}$ and $\frac{D'}{D}$, become infinite and the markups converge to zero. Deposit and lending rates converge to the Federal Funds rate minus or plus the marginal cost, as follows:

$$ r^d \to f - \phi^d, \quad r^l \to f + \phi^l \quad (23) $$

Under the frictionless benchmark, banks function as the bond market, passing through the interest rate changes to the exact same degree.

### 4.4.2. Imperfect competition

When competition is imperfect, market power creates a wedge between the Federal Funds rate and the rates at which banks borrow and lend. Monetary policy can affect the market power of banks by influencing the relative attractiveness of bank deposits or loans relative to other outside options available to households or firms.

In the model, bank deposits face competition from both bonds and cash. Investors get higher returns from investing in bonds but endure low liquidity. On the contrary, cash holdings offer high liquidity but zero return. Bank deposits are somewhere in between.

---

10In reality, the Federal Funds rate is slightly higher than the risk-free Treasury yield because of the default risk of the bank. However, we assume there is no default by the bank, so these two rates are equal.
offering investors both liquidity and some non-zero return. When the interest rate is high, the opportunity cost of holding cash increases and investors move out of cash and into bank deposits and bonds. Consequently, banks enjoy an outward shift in their deposit demand function and they can charge larger markup on deposits (e.g., Drechsler, Savov, and Schnabl 2017), so:

$$\frac{\partial}{\partial f} \left( \frac{D'}{D} \right)^{-1} > 0.$$ (24)

In the lending market, an increase in the Federal Funds rate makes bank loans less attractive to firms relative to the outside option of not borrowing. Therefore, total lending shrinks and banks optimally lower the markups they on loans to mitigate the effect of lower lending demand.

$$\frac{\partial}{\partial f} \left( \frac{-B'}{B} \right)^{-1} < 0.$$ (25)

4.4.3. Balance sheet frictions

In the frictionless benchmark, the deposit market and loan market are entirely separable because the bank can costlessly use non-reservable borrowing and government securities as buffers. Now consider the case in which banks face balance sheet frictions, so they incur additional costs when using non-reservable borrowing. Banks’ optimization becomes

$$\Pi = \max_{\{r^l, r^d\}} r^l B (r^l) - r^d D (r^d) - \phi^l B (r^l) - \phi^d D (r^d) - f (B (r^l) - D (r^d)) - \Phi(N),$$

where $\Phi(N)$ is the cost of non-reservable borrowing or investing excess funding and $N = B - D$ is the funding imbalance. In the presence of balance sheet frictions, the bank cannot costlessly replace the lost deposits with wholesale borrowing. Therefore, shocks to deposits will be transmitted to loans.
4.4.4. Reserve requirement

Now consider the case in which banks face reserve regulation that requires that for every dollar of deposits, the bank needs to keep a fraction, $\theta$, of these deposits as reserves. Assuming that the interest on reserves is zero, banks’ optimization becomes

$$
\Pi = \max_{\{r^l, r^d\}} r^l B (r^l) - r^d D (r^d) - \phi^l B (r^l) - \phi^d D (r^d) - f (B (r^l) - D (r^d))
$$

s.t. $R \geq \theta D (r^d)$

Because the interest on reserves is zero, the reserve constraint is binding. We can solve for the optimal deposit rate as

$$
r^d = f - \phi^d - \left( \frac{D^d}{D} \right)^{-1} - \theta f.
$$

(26)

Here we see that higher Federal Funds rates increase the opportunity cost of holding reserves, $\theta f$, which lowers deposit rates. Lower deposit rates, in turn, reduce the quantity of deposits and optimal supply of loans.

4.4.5. Capital regulation

Now consider the case in which banks face capital regulation that requires the bank capital to exceed a certain fraction of bank assets. In this case, banks’ optimization problem becomes

$$
\Pi = \max_{\{r^l, r^d\}} r^l B (r^l) - r^d D (r^d) - \phi^l B (r^l) - \phi^d D (r^d) - f (B (r^l) - D (r^d)),
$$

s.t. $E_0 + (1 - \tau_c)\Pi \geq \kappa B (r^l)$.

In the presence of capital regulation, shocks to bank capital affect lending capacity. One way that monetary policy affects bank capital is through maturity mismatch. Because deposits are short-term, an increase in the Federal Funds rate raises the rate that the bank has to pay
on all deposits. However, loans are long-term, so only a fraction of loans matures, with the remaining outstanding loans commanding a lower rate. Hence, an increase in the Federal Funds rate temporarily reduces bank capital and tightens the bank capital constraint in equation (15).

Another way that monetary policy affects bank capital is through market power. When the Federal Funds rate increases, bank profits from the deposit market increase, as the competition from cash lessens, but bank profits from the loan market decrease as borrowers are less willing to borrow at higher rates. The effect from the deposit market is likely to dominate the loan market effect when rates are very low, and especially, when rates are near the zero lower bound, leading to a tighter capital constraint in this region.

5. Estimation

5.1 Estimation procedure

We divide the estimation procedure into two stages. In the first stage, we estimate the demand elasticities and liquidity values for deposits and loans following Berry, Levinsohn, and Pakes (1995). In the second stage, we estimate the remaining parameters describing banks’ balance sheet frictions using simulated method of moments (SMM).

We first parameterize the quality of each option as a function of characteristics, $q^k_j = \beta^k x_j + \xi_j^k$, $k = d, l$, where $x_j$ is a vector of bank characteristics that includes the number of branches, the number of employees per branch, banks fixed effects, and time fixed effects. $\xi_j^k$ is an unobservable demand shock associated with product $j$. Next, we allow for heterogeneity in rate sensitivity in the deposit market, so each individual depositor’s rate sensitivity can be written as a mean rate sensitivity and a deviation from the mean, $\alpha_i = \alpha + \sigma_\alpha v_i$, where $v_i$ follows a uniform distribution. We assume the sensitivity to non-rate characteristics is homogeneous across both borrowers and depositors. Taken together, the demand functions
for bank deposits and loans are characterized by the preference parameters, \((\alpha^k, \beta^k, \sigma^k_\alpha)\), where \(k = d, l\). For simplicity, we drop the superscript indicating the deposit or loan market in the following discussion.

We use the methods from Berry, Levinsohn, and Pakes (1995) to estimate demand parameters, \(\Theta = (\alpha, \beta, \sigma_\alpha)\). First, we divide the parameters into linear parameters, \((\alpha, \beta)\), and non-linear parameters, \(\sigma_\alpha\). Second, for a given value of \(\sigma_\alpha\), there is a relation between mean utility, \(E[u_{ij}] = u_j = \alpha r_j + \beta x_j + \xi_j\), and the observed market share, \(s_0\), given by \(s(u|\sigma_\alpha) = s_0\), where \(s(.)\) is the market share equation as defined in equations (2) and (5). Third, we solve for the implicit function, \(s^{-1}(.)\), using the nested fixed-point algorithm described in Nevo (2001). Fourth, using this implicit function, we can solve for the unobservable demand shocks as functions of the observable market share and the demand parameters, as follows:

\[ \xi(\Theta) = s^{-1}(s_0|\sigma_\alpha) - (\alpha r_j + \beta x_j) \]

A key challenge in identifying the demand parameters is the natural correlation between deposit rates and unobservable demand shocks, \(\xi_j\). Following the industrial organization literature (Nevo 2001), we use a set of supply shifters, \(c_j\), as instrumental variables. Our particular instruments are bank salaries and non-interest expenses related to the use of fixed assets. Our identifying assumption is that these supply shifters are orthogonal to unobservable demand shocks and thus shift the supply curve along the demand curve, allowing us to trace out the slope of the demand curve.

Formally, define \(Z = [x, c]\), where \(x\) is a vector of bank characteristics and \(c\) is a vector of supply shifters. The moment condition for this estimation is the orthogonality condition between the unobservable demand shocks, \(\xi_j\) and the exogenous variables, \(z_j\), as follows:

\[ E[\xi_j z_j] = 0. \]

Define \(W\) as a consistent estimate of \(E[Z'\xi\xi'Z]\). The GMM estimator of the demand pa-
rameters is then given by:

\[ \hat{\Theta} = \arg\min_{\Theta} \xi(\Theta)' Z' W^{-1} Z \xi(\Theta). \]

The data used for the deposit demand estimation include each bank’s deposit market share, the proportions of cash and bonds in the household portfolio, each bank’s deposit rate,\(^{11}\) and non-rate bank characteristics such as the number of branches and the number of employees per branch. We also include bank and time fixed effects. The data used for the loan demand estimation include loan market shares for each bank, the corporate bonds market share, the each bank’s lending rate, and the non-rate characteristics.

We then plug the first-stage estimates of the deposit and loan demand functions into the model for the second stage SMM estimation. For this stage, we have to make one further simplification. Our data contain a large number of very small banks. This feature of the data poses a challenge because solving a model with a number of banks equal to the number of banks in our data would intractable. Therefore, we solve for an equilibrium with \( \hat{J} \) ex ante symmetric representative banks, where the number of representative banks \( \hat{J} \) is calibrated to match the HHI in the data. Because the size distribution has a heavy left tail, this approach substantially reduces the number of banks in the model while keeping the market concentration similar to that in the data. An alternative approach is to limit the sample to the largest banks. Our results are robust to the alternative approach.

Next, because we have a large number of non-rate bank characteristics that enter linearly in the utility function, we summarize these non-rate characteristics with a composite index that we interpret as “quality.” For simplicity, we assume quality is the same for all the

\(^{11}\) We use a weighted average of deposit rates for different types of deposits, where the weights are the relative quantities of each deposit type.
representative banks. The quality value can be calculated using the following formula:\(^\text{12}\)

\[
\hat{q} = \log \left( \frac{1}{J} \sum_{j=1}^{J} \exp(x_j \hat{\beta}) \right). \tag{27}
\]

With the quality value, we parameterize the deposit and loan demand functions as:

\[
s_j = \sum_{i=1}^{I} \mu_i \sum_{m \in A} \exp \left( (\hat{\alpha} + \hat{\sigma}_\alpha v_i) r_j + \hat{q}_j \right) \sum_{m \in A} \exp \left( (\hat{\alpha} + \hat{\sigma}_\alpha v_i) r_m + \hat{q}_m \right). \tag{28}
\]

\(\hat{\alpha}\) and \(\hat{\sigma}_\alpha\) are the mean and standard deviation of the deposit or loan rate sensitivity estimated from the first stage. Correspondingly, \(v_i\) and \(\mu_i\), \(i = 1, 2, \ldots, I\) are a discrete approximation of a uniform distribution. \(q_j\) is the quality value associated with option \(j \in 0, 1, \ldots, J + 1\).

In the deposit market, we normalize the quality value of cash to zero, and we denote by \(q^d_d\) and \(q^d_b\) the quality values of bank deposits and short-term bonds, respectively. In the loan market, we normalize the quality of bonds to zero, and we denote by \(q^l_l\) and \(q^l_n\) the quality values of loans and not borrowing, respectively. Note that the quality value of not borrowing cannot be estimated from the demand estimation because we do not observe its share. Therefore, we relegate this parameter to SMM.

In the second stage, we estimate five additional parameters using simulated method of moments (SMM), which chooses parameter values that minimize the distance between the moments generated by the model and their analogs in the data. We use eight moments to identify the remaining five model parameters. Parameter identification in SMM requires choosing moments whose predicted values are sensitive to the model’s underlying parameters. Our identification strategy ensures that there is a unique parameter vector that makes the model fit the data as closely as possible.

First, we use banks’ average non-reservable borrowing as a fraction of their deposits to

\(^{12}\)Alternatively, we can directly use the characteristics of the \(N\) largest banks in the data and ignore the smaller banks. This alternative approach biases the HHI in the model upwards, but the magnitude of the bias becomes quite small if \(N\) is larger than 10. The small bias occurs because the 10 largest banks in the United States account for a disproportionately large market share, so ignoring the small banks has a limited impact on the market equilibrium in the national market.
identify the cost of holding non-reservables ($\phi^N$). Intuitively, larger financing costs induce banks to finance loans mainly through deposits, and less via borrowing. Next, we use the average deposit and loan spreads to identify banks’ marginal costs of generating deposits ($\phi^d$) and servicing loans ($\phi^l$). Deposit spreads are defined as the difference between the Federal Funds rate and deposit rates, while loan spreads are the difference between loan rates and Treasury yields matched by maturity. In our model, banks with market power optimally choose to pass a fraction of their operating costs onto the depositors and borrowers. Hence, higher operating costs lead to monotonically higher spreads that banks charge in the deposit and lending markets. In addition, banks’ market power also determines the fraction of banks’ marginal costs that get passed onto customers. Market power depends critically the Federal Funds rate, as the attractiveness to households of alternative investments, as such cash and long-term bonds, changes with the Federal Funds rate. Therefore, we also include the correlation between the Federal Funds rate and both loan and deposit spreads to ensure that our model captures this important mechanism. Next, we use banks’ average dividend yield to identify the discount rate, $\gamma$. Intuitively, a high discount rate makes the banks impatient, so they pay out a larger fraction of their profit to shareholders instead of retaining it to finance future business. Finally, to identify the value of firms’ outside option of not borrowing, $q^l_n$, we include banks’ average loan to deposit ratio and the sensitivity of total corporate borrowing to the Federal Funds rate. These two moments suit this purpose because when the outside option becomes less valuable, its market share remains low regardless of the current Federal Funds rate. Thus, the sensitivity of the aggregate corporate borrowing to the Federal Funds rate should fall as $q^l_n$ falls. In addition, a high loan-to-deposit ratio should be inversely related to $q^l_n$ because when aggregate borrowing from the corporate sector is high, bank loans face proportionally higher demands.
5.2 Estimation Results

Table 4 presents the point estimates for the 22 model parameters. In Panel A, we start with the parameters that we can directly quantify in the data. Specifically, we set the corporate tax rate to its statutory rate of 35%. Capital regulation stipulates that banks keep no less than 6% of their loans as book equity. Reserve regulation requires a 10% reserve ratio for transaction deposits, 1% for saving deposits, and 0% otherwise. In our model, we only have one type of deposit, so our estimate of the deposit ratio is a weighted average of these three requirements, where the weights are the shares of a particular type of deposit in total deposits. We model the Federal Funds rate and the bank-level loan default rate as log AR(1) processes, and we directly calculate their means, standard deviations, and autocorrelations from the data. Finally, we set the maturity of loans in our model to average loan maturity in the data, which is approximately five years.

Panel B in Table 4 presents the demand parameters from the first stage BLP estimation.\textsuperscript{13} Not surprisingly, we find that depositors react favorably to high deposit rates while borrowers react negatively to high loan rates. Both yield sensitivities are precisely estimated, the economic magnitudes are significant as well. A 1% increase in the deposit rate increases the market share of a bank by approximately 0.8%, while a 1% increase in the loan rates decreases bank market share by 0.9%.\textsuperscript{14} We also find that depositors exhibit significant dispersion in their rate sensitivity. We also estimate depositors’ and borrowers’ sensitivities to non-rate bank characteristics such as the number of branches and the number of employees per branch. The estimates are also both statistically and economically significant. A 1% increase in the number of branches increase bank market share by 0.868% in the deposit market and 1.117% in the loan market. In comparison, the sensitivity to the number of employees per branch is

\textsuperscript{13}Detailed estimation results are presented in Table 6.

\textsuperscript{14}Under the assumption that there is no heterogeneity in yield sensitivity, mean utility is proportional to the log market share, $u_j - u_{outside} = \log(s_j) - \log(s_{outside})$. If the bank is small enough so that we can ignore the effect on the outside market share, the sensitivity coefficient can be approximately interpreted as the marginal effect of an increase in the corresponding characteristic.
smaller. A 1% increase in the number of employees per branch increases bank market share by 0.587% in the deposit market and 0.694% in the lending market. Using these estimates combined with bank and time fixed effects, we can calculate the implied quality parameter using (27), which we plug into the second-stage SMM estimation.

Panel C in Table 4 presents the balance sheet parameters from our second stage SMM estimation. We find that banks have a subjective discount rate of 5%, which is only slightly higher than the average Federal Funds rate observed in the data. Given the discount rate, banks pay out 2.6% of their equity value as dividends. We also find the cost of non-reservable borrowing both statistically and economically significant. At the average amount of non-reservable borrowing (30%), a marginal dollar of non-reservable borrowing costs the bank 0.6 cents above the cost implied by the prevailing Federal Funds rate. Note that the average deposit spread is 0.8%. Because banks equate the marginal costs of their funding sources, these numbers imply the marginal cost of expanding deposit averages 1.4%, suggesting a large role for deposit market power.\(^{15}\) This result implies that banks cannot easily replace deposits with other funding sources. Therefore, shocks to bank deposits are likely to be transmitted to bank lending. Finally, we find that banks incur a 0.7% cost of maintaining deposits and a 0.9% cost of servicing their outstanding loans.

Table 5 compares the empirical and model-implied moments. The model is able to match closely the banks’ market shares, average spreads, and the sensitivity of the Federal Funds rate to the deposit spread. In both the data and the model, banks borrow non-reservable securities, which amount to 30% of their total deposit intake. The spread that banks charge in the deposit market is significantly lower than the spread they receive in the loan market. This result arises because as the Federal Funds rate approaches zero, bank deposits face increasing competition from cash. Thus, banks market power falls and deposit spreads become compressed. A 1% decrease in the Federal Funds rate decreases the deposit spread by 30 basis points. However, as the Federal Funds rate falls lower, loan demand rises. A 1%

\(^{15}\)The marginal cost of non-reservable borrowing is \(\frac{\partial \Phi}{\partial N} = 2 \phi^N N = 2 \times 0.05 \times 0.3 = 0.03.\)
decrease in the Federal Funds rate increases loan spreads by 25 basis points. These results are consistent with our intuition and the data.

6. Counterfactuals

6.1 Decomposing Monetary Policy Transmission

Now we examine the quantitative forces that shape the relation between monetary policy, as embodied in changes in the Federal Funds rate, and aggregate bank lending. To this end, we start with the baseline model in row (1) of Table 7, where we see that on average in our model, a one percent change in the Federal Funds rate translates into a 3.88% decrease in aggregate lending. In the column labeled “Aggregate Lending,” we have normalized lending to 100% for this baseline case.

We proceed by eliminating the banks’ local market power and the regulatory constraints one by one to examine the cumulative effect of removing these frictions. As such, we analyze how the absence of each model ingredient influences aggregate lending in the economy and the transmission of the Federal Reserve’s monetary policy.

Row (2) presents the results from a version of the model without a reserve requirement. The nearly identical results imply that the reserve regulation has a minimal effect on banks’ lending decisions.

In row (3), we remove from the model banks’ market power in the deposit market. In this case, banks receive a fixed lump-sum profit equal to their oligopolist profit in the baseline case, and they use marginal cost pricing for deposit-intake decisions. Namely, they set the deposit rate equal to the Federal Funds rate minus the bank’s marginal cost of servicing deposits, and they take as many deposits as they are willing, given that deposit rate. If deposit market power is in place, when the Federal Funds rate increases, banks enjoy higher market power in the deposit market as a result of the decreased competitiveness from cash.
They react by charging higher deposit spreads and lowering the amount of deposit intake. Banks’ lending decisions partially echo this decline in deposit in-take because otherwise, when the amount of lending exceeds deposits, banks need to use expensive non-reservable borrowing to finance their loans. Thus, the bank’s market power, combined with the non-reservable borrowing cost, contribute to a negative relation between banks’ lending and the Federal Funds rate. Our results confirm this intuition. Once we eliminate market power in the deposit market, bank lending becomes less sensitive to change in the Federal Funds rate. A 1% increase in the Federal Funds rate causes a 2.57% decrease in aggregate lending. This sensitivity is 30% smaller than the 3.81% sensitivity observed in the baseline case. Finally, this result is important in that it highlights the interconnectedness of banks’ deposit taking and lending businesses. Banks’ market power in the deposit market gets passed on to the loan market and contributes to the sensitivity of bank lending.

Does the above result imply that bank market power plays a quantitative important monetary policy transmission, relative to other candidate transmission mechanisms? To answer this question, we compare the magnitudes in line (3) to the effects of relaxing the capital requirement, the results of which are in line (4). We find that without capital requirement, the change in the Federal Funds rate translates almost one-to-one into a change in bank loans, that is the sensitivity of bank loans to the Federal Funds rate drops sharply. A comparison of the results in lines (3) and (4) shows that the capital requirement enhances monetary policy transmission by 1.62% (2.57% − 0.95%). This effect is roughly a quarter larger than the effect of the deposit market power. Of course, this 1.62% magnitude captures both the effects of the capital requirement itself and also of its interaction with bank market power. More specifically, when the Federal Funds rate goes up, bank capital takes a hit because of the maturity mismatch. The profit resulting from bank’s market power also changes, thus interacting with the capital requirement.

Finally, we turn to banks’ market power in the lending market. Our results show that having market power in the lending market has a big impact on the quantity of aggregate
lending. The magnitude is consistent with the sizable spread that banks charge. In both the data and our baseline model, banks charge an average loan spread of 2.7%, which is significantly higher than the expected default cost plus the marginal cost of servicing loans. Once the banks switch to marginal cost pricing, the aggregate amount of lending in the economy goes up by 34%, from 128% of the baseline to 193% of the baseline. At the same time, removing banks’ loan market power also makes the aggregate quantity of loans more sensitive to the Federal Funds rate. This sensitivity goes up from $-0.95\%$ in the case in which loan market power is present to $-1.38\%$ in the case in which banks use marginal cost pricing in both the deposit and loan markets.

### 6.2 Reversal Rate

In our previous analysis, we did not break down the effects of changes in the Federal Funds rate as a function of the rate level. We now turn to this question in Figure 4, which shows the amount of bank lending for different levels of the Federal Funds rate. Overall, and as expected, there is a negative relationship between the Federal Funds rate and the amount of lending. However, the negative relation is reversed in the region where the Federal Funds rate is close to zero.

To understand this pattern, we also plot in Figure 4 the level of bank capital and the optimal amount of bank lending in a world with no capital requirements. We find that aggregate bank capital in the economy is inversely U-shaped. When the Federal Funds rate is above the 2.27% threshold, an increase in the Federal Funds rate has the usual effect of tightening lending. However, when the Federal Funds rate is below the 2.27% threshold, an increase in the Federal Funds rate actually has the opposite effect of expanding lending. We call the region in which the Federal Funds rate is below 2.27% a “reversal rate” environment.

The pattern in bank capital is central to answering the question of why monetary policy, as embodied in changes in the Federal Funds rate, has opposite signs on the two sides of the threshold. To understand this connection, note that optimal lending is the smaller of
two quantities: desired lending and feasible lending. The former is the optimal amount of lending in the absence of a capital requirement, and the latter is maximal lending permitted by bank’s equity capital. In equilibrium, desired lending is always decreasing in the Federal Funds rate, as high funding costs deter firms from borrowing. Hence, in high-rate regions, the capital requirement is slack, and the actual quantity of lending is the desired amount. On the other hand, when the Federal Funds rate is low, desired lending exceeds that allowed by the bank’s equity. Thus, the capital requirement binds, and the actual lending tracks the bank’s equity capital, which increases in the Federal Funds rate. Figure 4 confirms this intuition. When the Federal Funds rate is above 2.27%, actual lending and desired lending closely track each other, whereas when the Federal Funds rate is below this threshold, actual lending falls short of the desired quantity.

The excess of desired over capital-constrained lending makes sense given firms’ equilibrium high demand for loans in a low interest rate environment. However, the question remains of the forces behind the positive relation between bank equity and the Federal Funds rate when the latter is low. This result stems from the relative magnitudes of profits from lending and deposit taking. First, changes in the Federal Funds rate have opposite effects on bank profits in the deposit and lending markets. When the Federal Funds rate is high, holding cash is highly unattractive from the depositors’ point of view, and banks face consistent weak competition from cash in the deposit market. Hence, bank profit from the deposit market increases in the Federal Funds rate. In contrast, bank profit from lending decreases in the Federal Funds rate, as higher funding costs makes the firms’ outside option of not investing more appealing. Our parameter estimates imply that when the Federal Funds rate is low, the effect on profits from the deposit market dominate the effects from the lending market. Thus, an increase in the Federal Funds rate leads to higher bank profits, which in turn feed into the equity capital base, as banks find it optimal to shore up capital to deflect future financing costs by not paying out all of their profits to shareholders.

To understand more fully the dynamic response of bank lending to monetary policy
shocks, in Figure 5, we simulate the response of bank lending to a shock to the Federal Funds rate. The economy starts at time zero in an initial steady state with the Federal Funds rate equal to the inflection point of 2.27%. At time one, the Federal Funds rate either increases or decreases by two standard deviations, and it stays at that level afterwards until the economy reaches a new steady state. Each variable in the graph is scaled by its level in the old steady state, that is, when the Federal Funds rate is 2.27%.

When the Federal Funds rate increases, banks face less competition from households’ demand for cash in the deposit market. Thus, they can behave more like monopolists by charging higher spreads and cutting the amount of deposits. Lower deposit intake increases the banks’ marginal cost of lending because when their lending exceeds their capital plus deposit intake, they must turn to the market for non-reservable borrowing, in which they face increasing marginal external financing costs. A positive shock to the Federal Funds rate also increases the cost of capital in corporate sector, making firms more likely to switch to the outside option of not borrowing. Both effects shrink the amount of lending. Note that the deposit quantity converges almost instantly to the new steady state, while the loan quantity first overshoots and then reverts slowly back to the new steady state. Intuitively, the bank’s equity takes a hit with a positive shock to the Federal Funds rate because of the maturity mismatch on its balance sheet. It takes time for the bank to restore its capital stock by retaining profits. Loan quantity converges even more slowly as the bank only replaces a fraction $\mu$ of its long-term loans each period.

When the Federal Funds rate decreases and approaches the zero lower bound, banks face increasingly intense competition from cash in the deposit market. As a result, the spread that banks can charge in the deposit market is squeezed, leading to a sharp drop in banks’ profits. Given the high persistence in the Federal Funds rate, this lower profit translates into slower retained earnings accumulation over time and leads to decreased bank capital. In the new steady state, banks take large deposits in the deposit market, which can support increased lending. However, banks cannot lend more because their capital requirements tighten in the
extremely low Federal Funds rate environment. Because total lending decreases, the banks face less of a need to seek external financing, and they use less non-reservable borrowing. As before, loan quantity initially overshoots because the longer maturity of bank loans induces a temporary relaxation in the capital requirement.

It is interesting to note that in the two graphs in Figure 5, the loan amount decreases when the Federal Funds rate changes in either direction. Although the loan amount moves in the same direction, the driving force is different in the two cases. When the Federal Funds rate increases, loans fall because higher spreads in the deposit market discourage households from making deposits. Banks turn to non-reservable borrowing to fund loans, and because of increasing costs in this market, the amount of lending is highly dependent on the quantity of deposits. Instead, when the Federal Funds rate decreases, the loan amount decreases because of the binding capital requirement, and it echoes changes in the banks’ profit accumulation. The distinct driving forces underlying the above two plots are also reflected by the differential trends in banks’ deposit quantity and non-reservable borrowing.

7. Conclusion

The U.S. banking sector has experienced an enormous amount of consolidation. The market share of the top five banks has increased from less than 15% in the 1990s to over 45% as of 2017. This consolidation begs the question of whether bank market power has a quantitatively important effect on the transmission of monetary policy. We study this question by formulating and estimating a dynamic banking model with regulatory constraints, financial frictions, and imperfect competition. This unified framework is useful because it allows us to gauge the relative importance of different monetary policy transmission channels.

In our counterfactuals, we show that the channel related to reserve requirements has minor quantitative importance. In contrast, we find that channels related to bank capital requirements and to market power are very important. We also find an interesting interaction
between the market power channel and the bank capital channel. If the Federal Funds rate is low, depressing it further can actually contract bank lending, as the drop in bank profits in the deposit market has a negative impact on bank capital. Lastly, we show that financial frictions on banks’ balance sheet play an important role in transmitting shocks from bank deposits to bank loans.

Our work contributes to the historical debate between the “money view” and the “lending view” of banking monetary policy transmission (Romer and Romer 1990; Kashyap and Stein 1995). The “money view” postulates that the quantity of deposits matters for economic activity as a medium of exchange and that monetary policy influences deposit quantity through bank reserves. While our results do not negate the premise that the quantity of deposits matters, we show that the channel through which monetary policy affects bank deposits is increasingly through the market power channel rather than the reserve channel, at least after the 1990s.

An alternative view of monetary transmission is the “lending view”, which rests on the idea that monetary policy also has a separate effect on the supply of loans by influencing the quantity of deposits. Romer and Romer (1990) argue that the “lending view” is unlikely to be important because banks can always easily replace deposits with external financing. In contrast, Kashyap and Stein (1995) argues that the banks can face costly external financing. Our study sheds new light on this debate, as the structural estimation approach allows us to infer the degree of the bank financing costs from the relative size of their non-reservable borrowing and deposit taking. We find the magnitude of this cost is economically significant and frictions related to bank balance sheets play an important role in the transmission of monetary policy.

This table reports summary statistics of the sample for BLP estimation. The sample period is from 1994 to 2017. Deposit share and loan share are computed taking the entire United States as a unified market. The total size of the deposit market is defined as the sum of deposits, cash, and bonds held by all the U.S. households. The total size of the loan market is defined as the sum of bank loans and corporate bonds issued by the U.S. firms. Deposit and loan rates are imputed using the interest expense and income from Call report. Expense of fixed assets and salary are scaled by total assets. Deposit share, loan share, deposit rates, loan rates, expense of fixed assets and salary are reported in percentage. The data is from Call report and FDIC Summary of Deposits.

This table reports the estimates of the relation between bank stock returns and monetary policy shocks on FOMC Days. Monetary shocks are measured by the daily change in the two-year Treasury yield on FOMC days. HHI is the Herfindahl-Hirschman index of the local deposit market in which the bank operates. A local deposit market is defined as a Metropolitan Statistical Area (MSAs). If a bank operates in several MSAs, the bank-level HHI is the weighted average of local HHI, weighted by the deposits of the bank in the local market. The sample includes all publicly traded U.S. banks from 1994 to 2017. We exclude observations during the burst of dot-com bubble (2000-2001) and the subprime financial crisis (2007-2009). The standard errors are clustered by time.

This table reports the estimated parameters of the deposit and loan demand. The first column reports parameters of deposit demand. The second column reports parameters of loan demand. Yield sensitivity ($\alpha$) refers to the average sensitivity of the depositors (firms) to deposit rates (loan rates). Log No. of Branches ($\beta_1$) refers the sensitivity of the depositors (firms) to log number of branches that each bank has. Log No. of Employees ($\beta_2$) refers the sensitivity of the depositors (firms) to log number of employees per branch. Yield sensitivity dispersion ($\sigma_\alpha$) refers to the dispersion in the sensitivity of the depositors to deposit rates (the dispersion is set to 0 for firms). The sample includes all the U.S. commercial banks from 1994 to 2017 with domestic branches higher than 10. The data is from the Call report and the Summary of Deposits.

</table>

This table depicts a series of counterfactual experiments in which we examine the cumulative effect of removing frictions from our model on two important quantities. The first is the sensitivity of loans to the Federal Funds rate (FFR), and the second is the aggregate amount of borrowing, which is normalized to 100% in the baseline case. Each line of the table presents the results from eliminating the corresponding friction.
Figure 1: Loan-to-Deposit Ratios for U.S. Banks
This figure plots the loan-to-deposit ratio of U.S. banks after the start of five recessions from 1973 to 2017. The x-axis is the month since the start of recession and the y-axis the loan-to-deposit ratio. We normalize the ratio in month 0 to 1. We plot the path of the ratio until the ratio recovers to the pre-recession level. The data is retrieved from FRED database of the Federal Reserve Bank of St. Louis.
Figure 2: Monetary Policy Shocks and Bank Stock Returns
This figure provides the scatter plot of the bank industry excess stock returns against the daily change in two-year Treasury yield on FOMC days from 1994 to 2017. The excess stock return is defined as the difference between bank industry index return and the market return. The sample of the upper panel is when the Federal Funds rate is above 2% and the sample of the lower panel is when the Federal Funds rate is below 2%. We exclude observations during the burst of dot-com bubble (2000-2001) and the subprime financial crisis (2007-2009) because the stock returns are extremely volatile. The bank industry stock returns are retrieved from Kenneth French’s website and the two-year Treasury yield is retrieved from FRED database of the Federal Reserve Bank of St. Louis.
Figure 3: Timeline within a Period
Figure 4: Fed Funds Rate and Bank Characteristics
This figure illustrates how bank capital and optimal lending vary with the Fed Funds rate. Banks’ optimal lending is calculated under two alternative cases: the baseline line where banks are subject to the capital regulation and an alternative unconstrained case where the capital regulation is removed. The Fed Funds rate is on the x-axis; bank characteristics, scaled by their respective steady state values (when the Fed funds rate is 0.02), is on the y-axis.
Figure 5: Impulse Response to Fed Funds Rate Shocks
This figure illustrates banks’ impulse response to Fed fund rate shocks. The economy starts at Year 0 when it is in the old steady state with the FFR equal to 0.02; In Year 1, the FFR either increases or decreases by two standard deviations, and it stays at that level afterwards until the economy reaches the new steady state. Each variable in the graph is scaled by the level in the old steady state (when FFR = 0.02).
