Endogenous Regime Switching Near the Zero Lower Bound

Kevin J. Lansing†

February 23, 2018

Abstract

This paper develops a New Keynesian model with a time-varying natural rate of interest (r-star) and a zero lower bound (ZLB) on the nominal interest rate. The representative agent contemplates the possibility of an occasionally binding ZLB that is driven by switching between two local equilibria, labeled the “targeted” and “deflation” regimes, respectively. Sustained periods when the real interest rate remains below the central bank’s estimate of r-star can induce the agent to place a substantially higher weight on the deflation forecast rules, causing the deflation equilibrium to occasionally become fully realized. I solve for the time series of stochastic shocks and endogenous forecast rule weights that allow the model to exactly replicate the observed time paths of the U.S. output gap, quarterly inflation, and the federal funds rate since 1988. The data since the start of the ZLB episode in 2008.Q4 are best described as a mixture of the two local equilibria. In model simulations, raising the central bank’s inflation target to 4% from 2% can reduce, but not eliminate, the endogenous switches to the deflation equilibrium.

Keywords: Natural rate of interest, New Keynesian, Liquidity trap, Zero lower bound, Taylor rule, Deflation.

JEL Classification: E31, E43, E52.

1 Introduction

The sample period from 1988 onwards is generally viewed as an example of consistent U.S. monetary policy aimed at keeping inflation low while promoting sustainable growth and full employment. Amazingly, the U.S. federal funds rate has been pinned close to zero for about one-fourth of the elapsed time since 1988. The U.S. economy is not alone in experiencing an extended period of zero or mildly negative nominal interest rates in recent decades.

Figure 1 plots three-month nominal Treasury bill yields in the United States, Japan, Switzerland, and the United Kingdom. Nominal interest rates in the United States encountered the zero lower bound during the 1930s and from 2008.Q4 though 2015.Q4. Nominal interest rates in Japan have remained near zero since 1998.Q3, except for the relatively brief period from 2006.Q4 to 2008.Q3. Nominal interest rates in Switzerland have been zero or slightly negative since 2008.Q4. Nominal interest rates in the United Kingdom have been approximately zero since 2009.Q1. Outside of these episodes, all four countries exhibit a strong positive correlation between nominal interest rates and inflation, consistent with the Fisher relationship.

Benhabib, Schmitt-Grohé and Uribe (2001a,b) show that imposing a zero lower bound (ZLB) on the nominal interest rate in a standard New Keynesian model gives rise to two long-run endpoints (steady states). The basic idea is illustrated in Figure 2, which is adapted from Bullard (2010). The two intersections of the ZLB-augmented monetary policy rule (solid red line) with the Fisher relationship (dashed black line) define two long-run endpoints. I refer to these as the “targeted equilibrium” and “deflation equilibrium,” respectively. The aim of this paper is to develop a quantitative New Keynesian model that can account for the pattern of inflation and interest rates observed in Figure 2 since 1988.

The model incorporates three types of persistent shocks: an aggregate demand shock, a cost push shock, and a shock to the agent’s discount factor that gives rise to movements in the real short-term interest rate. The long-run endpoint of the real interest rate process is allowed to shift over time. This feature captures the notion of a time-varying natural rate of interest (r-star). R-star is an important benchmark for monetary policy because it determines the real interest rate that policymakers should aim for once shocks to the economy have dissipated and the central bank’s macroeconomic targets have been achieved. The times series process

---

1 I use the terminology “long-run endpoints” rather than “steady states” because the model developed here allows for permanent shifts in the natural rate of interest which, in turn, can shift the long-run values of some macroeconomic variables.

2 Willamson (2017a) provides a discussion of the distinctions between the “natural,” “equilibrium,” and
for r-star in the model is calibrated to approximate the path of the U.S. natural rate series estimated by Laubach and Williams (2016).3

As is well known, the New Keynesian deflation equilibrium is locally indeterminate. I therefore consider a minimum state variable (MSV) solution that rules out sunspot variables and extra lags of fundamental state variables. The decision rules associated with the deflation equilibrium induce more volatility in the output gap and inflation in response to real interest rate shocks. Model variables in the deflation equilibrium have distributions with lower means and higher variances than those in the targeted equilibrium. But the significant overlap in the various distributions creates a dilemma for an agent who seeks to determine the likelihood that a string of recent data observations are drawn from one equilibrium or the other.

The representative agent in the model contemplates the possibility of an occasionally binding ZLB that is driven by switching between the two local equilibria. This view turns out to be true in the simulations, thus validating the agent’s beliefs. The agent constructs forecasts using a form of model averaging, where the time-varying forecast weights are determined by recent performance, as measured by the root mean squared forecast errors for the output gap and inflation (the two variables that the agent must forecast). Sustained periods when the exogenous real interest rate remains below the central bank’s estimate of r-star can induce the agent to place a substantially higher weight on the deflation forecast rules, causing the deflation equilibrium to occasionally become fully realized. These episodes are accompanied by highly negative output gaps and a binding ZLB, reminiscent of the U.S. Great Recession. But even outside of recessions or when the ZLB is not binding, the agent may continue to assign a nontrivial weight to the deflation equilibrium, causing the central bank to persistently undershoot its inflation target, similar to the U.S. economy since mid-2012.

I solve for the time series of stochastic shocks and endogenous forecast rule weights that allow the switching model to exactly replicate the observed time paths of the CBO output gap, quarterly PCE inflation, and the federal funds rate since 1988. The data since the start of the ZLB episode in 2008.Q4 are best described as a mixture of the two local equilibria. The model-implied weight on the targeted forecast rules starts to decline in 2008.Q4. At the end of the data sample in 2017.Q2, the weight on the targeted forecast rules is only 0.56, helping the switching model to account for the persistent undershooting of the Fed’s inflation target since mid-2012. The path of expected inflation from the switching model starts to decline after 2008.Q4 and remains below the Fed’s 2% inflation target at the end of the data sample.

“neutral” real rates of interest—terms that are often used interchangeably in the literature.

3Updated data are from www.frbsf.org/economic-research/files/Laubach_Williams_updated_estimates.xlsx.
This pattern is very similar to the 1-year expected inflation rate from inflation swap contracts.

The framework developed here is related to work by Aruoba and Schorfheide (2016) and Aruoba, Cuba-Borda, and Schorfheide (2018). These authors construct stochastic two-regime models in which the economy can switch back and forth between a targeted-inflation regime and a deflation regime, depending on the realization of an exogenous sunspot variable. They employ various model specifications to infer whether the interest rate and inflation observations in the data are more likely to have been generated by one regime or the other. Aruoba, Cuba-Borda, and Schorfheide (2018, p. 116) conclude that “the U.S. remained in the targeted-inflation regime during its ZLB episode, with the possible exception of the early part of 2009 where evidence is ambiguous.”

An important premise underlying the results of Aruoba, Cuba-Borda, and Schorfheide (2018) is that the observed data must come from one regime or the other. In contrast, the switching model developed here generates data that is a convex mixture of the two regimes. This is due to the time-varying forecasts weights assigned by the agent in the model. The forecast weights, in turn, influence the model-generated data. So, the deflation regime can influence the model-generated data even if the deflation equilibrium is never fully realized. Another key difference is that the probability of transitioning between regimes is endogenous here, and can be influenced by a change in the monetary policy rule or other model parameters. The switching model shares some similarities with the work of Sargent (1999) in which the economy can endogenously transition between regimes of high versus low inflation, depending on policymakers’ perceptions about the slope of the long-run Phillips curve. Here, the endogenous regime switching depends on the agent’s perceptions about the best forecast weights.

Another related paper is one by Dordal-i-Carrera et al. (2016). These authors develop a New Keynesian model with volatile and persistent “risk shocks” (i.e., shocks that drive a wedge between the nominal policy rate and the short-term bond rate) to account for infrequent but long-lived ZLB episodes. A risk shock in their model is isomorphic to a real interest rate shock here. Large adverse risk shocks are themselves infrequent and long-lived. As the binding ZLB episode becomes more frequent or more long-lived, the optimal inflation target increases. Unlike here, their analysis does not consider model solutions near the deflation equilibrium, but rather focuses on scenarios in which fundamental shocks are large enough to push the targeted equilibrium to a point where ZLB becomes binding.\(^4\) In contrast, the model developed here

\(^4\)This is also the methodology pursued by Reis\-schneider and Williams (2000), Schmitt-Grohé and Uribe
accounts for infrequent but long-lived ZLB episodes via endogenous switching between two local equilibria, i.e., the shock process itself is not the sole driving force for the infrequent and long-lived ZLB episodes.

As part of the quantitative analysis, I examine how raising the central bank’s inflation target can influence the ZLB binding frequency and the volatility of macro variables in the switching model. I find that even with an inflation target of 4%, the ZLB binding frequency remains elevated at 9.5% and the average duration of a ZLB episode is 11.7 quarters. Once the deflation equilibrium is taken into account, raising the inflation target is a less effective solution for avoiding ZLB episodes.

Numerous papers consider optimal monetary policy in response to a time-varying natural rate of interest. The models typically impose the ZLB (or effective lower bound), but the deflation equilibrium is ignored, i.e., the analysis is local to the targeted equilibrium. One finding from literature is that more uncertainty about the future natural rate implies looser monetary policy today or more policy inertia. Here I show that more policy inertia (i.e., a larger interest rate smoothing parameter in the Taylor-type rule) serves to decrease the ZLB binding frequency, but the episodes exhibit longer duration on average.

It has been suggested by some that the deflation equilibrium should be ignored because it may not be learnable using standard algorithms. A typical conclusion from the literature is that only the targeted equilibrium is locally (but not globally) stable under least squares learning. Recently, however, Arifovic, Schmitt-Grohé, and Uribe (2018) demonstrate that both equilibria can be locally stable under a form of social learning. In the last section of the paper, I introduce an adaptive learning algorithm in a simplified version of the model. When the agent estimates correctly specified decision rules, the algorithm quickly converges to the vicinity of the targeted equilibrium and remains there. But when the agent estimates decision rules that fail to control for two white noise shocks, the model exhibits low frequency switching between the two local equilibria. This pattern is qualitatively similar to that observed in the original switching model with full-knowledge.

2 Model

The framework for the analysis is a three equation New Keynesian model, augmented by a zero lower bound on the short-term nominal interest rate. The log-linear version of the standard New Keynesian model is taken to represent a set of global equilibrium conditions, with the only nonlinearity coming from the ZLB. The setup is a reduced form version of a fully-specified nonlinear New Keynesian DSGE model, but has the advantage of delivering transparency of the model’s dynamics.\(^7\)

Private-sector behavior is governed by the following equilibrium conditions:

\[ y_t = E_t y_{t+1} - \alpha [i_t - E_t \pi_{t+1} - r_t] + \nu_t, \]
\[ \pi_t = \beta E_t \pi_{t+1} + \kappa y_t + u_t, \]

where equation (1) is the representative agents’s consumption Euler equation and equation (2) is the Phillips curve that is derived from the representative firm’s optimal pricing decision. The variable \( y_t \) is the output gap (the log deviation of real output from potential output), \( \pi_t \) is the quarterly inflation rate (log difference of the price level), \( i_t \) is the short-term nominal interest rate, \( r_t \) is the exogenous real interest rate, and \( E_t \) is the expectations operator. In solving the model, \( E_t \) will correspond to rational expectations in the vicinity of the model’s long-run endpoints. Fluctuations in \( r_t \) can be interpreted as arising from changes in the agent’s rate of time preference or changes in the expected growth rate of potential output.\(^8\)

None of the results in the paper are sensitive to the introduction of a discount factor applied to the term \( E_t y_{t+1} \) in equation (1), along the lines of McKay, Nakamura, and Steinsson (2016). The terms \( \nu_t \) and \( u_t \) represent an aggregate demand shock and a cost-push shock, respectively, which evolve according to following laws of motion:

\[ \nu_t = \rho_{\nu} \nu_{t-1} + \epsilon_{\nu,t}, \quad \epsilon_{\nu,t} \sim N \left[ 0, \sigma_{\nu}^2 \left( 1 - \rho_{\nu}^2 \right) \right], \]
\[ u_t = \rho_{u} u_{t-1} + \epsilon_{u,t}, \quad \epsilon_{u,t} \sim N \left[ 0, \sigma_{u}^2 \left( 1 - \rho_{u}^2 \right) \right]. \]

The time series process for the exogenous real rate of interest is given by

\[ r_t = \rho_r r_{t-1} + (1 - \rho_r) r_t^* + \varepsilon_t, \quad \varepsilon_t \sim N \left( 0, \sigma_{\varepsilon}^2 \right), \]
\[ r_t^* = r_{t-1}^* + \eta_t, \quad \eta_t \sim N \left( 0, \sigma_{\eta}^2 \right). \]

\(^7\)Armenter (2016) adopts a similar approach in computing the optimal monetary policy in the presence of two steady states. Eggertsson and Sing (2016) show that the log-linear New Keynesian model behaves very similar to the true nonlinear model in the vicinity of the targeted equilibrium.

\(^8\)Specifically, we have \( r_t = -\log [\beta \exp (\zeta_t)] + \gamma E_t \Delta \tilde{y}_{t+1} \), where \( \zeta_t \) is a shock to the agent’s time discount factor \( \beta \), \( \tilde{y}_t \) is the logarithm of real potential output, and \( \gamma = \alpha^{-1} \) is the coefficient of relative risk aversion. For the derivation, see Hamilton, et al. (2016) or Gust, Johannsen, and Lopez-Salido (2017).
Equations (5) and (6) summarize a “shifting endpoint” time series process since the long-run endpoint $r_t^*$ can vary over time due to the permanent shock $\eta_t$. In any given period, $r_t$ can deviate from $r_t^*$ due to the temporary shock $\varepsilon_t$. The persistence of the “real interest rate gap” $r_t - r_t^*$ is governed by the parameter $\rho_r$, where $|\rho_r| < 1$. Kozicki and Tinsely (2012) employ this type of process to describe U.S. inflation. When $\rho_r = 1$, we recover the random walk plus noise specification employed by Stock and Watson (2007) to describe U.S. inflation.9

Using equation (5) to substitute out $r_t$ from equation (1) yields the following alternative version of the consumption Euler equation:

$$y_t = E_t y_{t+1} - \alpha [i_t - E_t \pi_{t+1} - r_t^*] + u_t + \alpha \varepsilon_t + \alpha \rho_r (r_{t-1} - r_{t-1}^* - \eta_t),$$  (7)

where the last three terms could be consolidated into a single aggregate demand shock. From this version, we can interpret $r_t^*$ as the unobservable “natural rate of interest,” i.e., the real interest rate that is consistent with full utilization of economic resources and steady inflation at the central bank’s target rate. This interpretation is consistent with the empirical strategies of Laubach and Williams (2016), Lubik and Matthes (2015), and Kiley (2015) which view the natural rate of interest as a longer-term economic concept. In contrast, empirical strategies that employ micro-founded New Keynesian models typically view the natural (or equilibrium) rate of interest as a short-term concept, more along the lines of the variable $r_t$ in equation (1).10 The real interest rate gap $r_t - r_t^*$ captures a concept that has been emphasized by Fed policymakers in recent speeches, namely, a distinction between estimates of the “short-term natural of interest” and its longer-term counterpart (Yellen 2015, Dudley 2015, and Fischer 2016). Here I will refer to $r_t^*$ as the natural rate of interest.

In the model, the agent’s rational forecast for the real interest rate gap at any horizon $h \geq 1$ is given by

$$E_t (r_{t+h} - r_{t+h}^*) = (\rho_r)^h (r_t - E_t r_t^*),$$  (8)

where $E_t r_t^*$ represents the current estimate of the natural rate computed using the Kalman filter so as to minimize the mean squared forecast error. When $|\rho_r| < 1$ as assumed here, the real interest rate gap is expected to shrink to zero as the forecast horizon $h$ increases. In

---

9 But unlike here, Stock and Watson (2007) allow for stochastic volatility in the permanent and temporary shocks.

10 See, for example, Barsky, Justiniano, and Melosi (2014), Cúrdia, et al. (2015), and Del Negro, et al. (2017).
Appendix A, I show that the Kalman filter expression for $E_t r_t^*$ is

$$E_t r_t^* = \lambda \left( \frac{r_t - \rho_r r_{t-1}}{1 - \rho_r} \right) + (1 - \lambda) E_{t-1} r_{t-1}^*$$

where $\lambda$ is the Kalman gain parameter and $\phi \equiv \sigma_n^2 / \sigma_z^2$. For the quantitative analysis, the values of $\rho_r$, $\sigma_n^2$, and $\sigma_z^2$ are chosen so that the time path of $E_t r_t^*$ from equation (9) approximates the path of the U.S. natural rate series estimated by Laubach and Williams (2016, updated) for the sample period 1988.Q1 to 2017.Q2. Their estimation strategy assumes that the natural rate exhibits a unit root, consistent with equation (6). Hamilton, et al. (2016) present evidence that the ex-ante real rate of interest $i_t - E_t \pi_{t+1}$ in U.S. data is nonstationary, but they find that the gap between the ex-ante real rate and their estimate of the world long-run real rate appears to be stationary. This evidence is also consistent with equations (5) and (6) which imply that real rate gap $r_t - r_t^*$ is stationary.

The central bank’s monetary policy rule is given by

$$i_t^* = \rho i_{t-1}^* + (1 - \rho) \left[ E_t r_t^* + \pi^* + g_1 (\pi_t - \pi^*) + g_2 (y_t - y^*) \right],$$

$$\pi_t = \omega \pi_t + (1 - \omega) \pi_{t-1},$$

$$i_t = \max \{0, i_t^*\},$$

where $i_t^*$ is the desired nominal interest rate that responds to deviations of recent inflation $\pi_t$ from the central bank’s target rate $\pi^*$ and to deviations of the output gap from its targeted long-run endpoint $y^*$. Recent inflation $\pi_t$ is an exponentially-weighted moving average of past quarterly inflation rates so as to approximate the compound average inflation rate over the past 4 quarters—a typical central bank target variable.\textsuperscript{11} Equation (13) is the ZLB that constrains the nominal policy interest rate $i_t$ to be non-negative. The parameter $\rho$ governs the degree of interest rate smoothing as $i_t^*$ adjusts partially each period toward the value implied by the terms in square brackets. Similar to the policy rule employed by Dordal-i-Carrera et al. (2016), equation (11) keeps track of past negative values of $i_t^*$, thereby exhibiting a form of commitment to keep interest rates “lower for longer” whenever the ZLB becomes binding.\textsuperscript{12}

The quantity $E_t r_t^* + \pi^*$ represents the targeted long-run endpoint of $i_t^*$. Including $E_t r_t^*$ in the policy rule implies that monetary policymakers continually update their estimate of the

\textsuperscript{11}Specifically, the value of $\omega$ is set to achieve $\pi_t \simeq [\Pi_{j=n}^3 (1 + \pi_{t-j})]^{0.25} - 1$

\textsuperscript{12}Alstadheim and Henderson (2006) and Sugo and Ueda (2008) formulate interest rate rules that can preclude the deflation equilibrium.
unobservable $r^*_t$. Support for this idea can be found in the Federal Open Market Committee's Summary of Economic Projections (SEP). Meeting participants provide their views on the projected paths of macroeconomic variables over the next three calendar years and in the longer run. Since the natural rate of interest is a longer-run concept, we can infer the median SEP projection for $r^*_t$ by subtracting the median longer-run projection for inflation from the median longer-run projection for the nominal federal funds rate. The median SEP projection for $r^*_t$ computed in this way has ratcheted down over time, as documented by Lansing (2016).\textsuperscript{13}

2.1 Long-run endpoints

The Fisher relationship $i_t = r_t + E_t \pi_{t+1}$ is embedded in the non-stochastic version of equation (1).\textsuperscript{14} Consequently, when $g_\pi > 1$, the model has two long-run endpoints (steady states) as shown originally by Benhabib, Schmitt-Grohé, and Uribe (2001a,b). The novelty here is that the long-run endpoints can shift due to shifts in $r^*_t$. Straightforward computations using the model equations yield the following long-run endpoints that characterize the “targeted equilibrium” and the “deflation equilibrium,” respectively.

<table>
<thead>
<tr>
<th>Targeted equilibrium</th>
<th>Deflation equilibrium</th>
</tr>
</thead>
<tbody>
<tr>
<td>$\pi_t = \pi^*$</td>
<td>$\pi_t = -r^*_t$</td>

</tr>
</tbody>
</table>

In the targeted equilibrium, long-run inflation is at the central bank’s target rate $\pi^*$ and the long-run output gap $y^*$ is slightly positive for typical calibrations with $0.99 < \beta < 1$. The long-run desired nominal policy rate $i^*_t$ conforms to the Fisher relationship and the ZLB is not binding such that $i_t = i^*_t > 0$, provided that $r^*_t > -\pi^*$. In the model simulations, I impose bounds on fluctuations in $r^*_t$ that are based on the range of natural rate estimates obtained by Laubach and Williams (2016) for the sample period since 1988. In the deflation equilibrium, the long-run inflation rate, the long-run output gap, and the long-run desired nominal interest rate are all negative when $r^*_t > 0$.

\textsuperscript{13}Gust, Johannsen, and Lopez-Salido (2017) show that a Taylor-type rule that includes a time-varying intercept that moves with perceived changes in the equilibrium real interest rate can achieve results that are similar to optimal discretionary policy. Carlstrom and Fuerst (2016) compute the optimal response coefficient on the natural rate of interest in a Taylor-type rule.

\textsuperscript{14}Cochrane (2017), Williamson (2017b), and Garín, Lester, and Sims (2018) show that Fisherian effects can dominate the short-term comovement between the nominal interest rate and inflation in standard New Keynesian models. Uribe (2017) examines the strength of Fisherian effects in a structural VAR framework using data for the U.S. and Japan.
2.2 Local linear forecast rules

Given the linearity of the model aside from the ZLB, it is straightforward to derive the agent’s rational decision rules for $y_t$ and $\pi_t$ in the vicinity of the long-run endpoints associated with each of the two equilibria. For the targeted equilibrium, the local decision rules are unique linear functions of the state variables: $r_t$, $E_t r_t^*$, $\pi_{t-1}$, $i_t^*$, $\nu_t$, and $u_t$. For the deflation equilibrium, I solve for the minimum state variable (MSV) solution which abstracts from extraneous sunspot variables and extra lags of fundamental state variables.\(^{15}\)

Given the local linear decision rules, we can construct the agent’s local linear forecast rules for $y_{t+1}$ and $\pi_{t+1}$ in each of the two equilibria. As shown in Appendices B and C, the local linear forecast rules depend on the realizations of $\pi_t$ and $i_t^*$. But since $\pi_t$ and $i_t^*$ depend in part on the agent’s forecasts, there exists simultaneity between the forecasted and realized values of $\pi_t$ and $i_t^*$. To handle this simultaneity in the numerical simulations, I substitute the local linear forecast rules into the global equilibrium conditions (1) and (2). I allow for an occasionally binding ZLB by making the substitution $i_t = 0.5 i_t^* + 0.5 \sqrt{(i_t^*)^2}$ in equation (1). Together with the monetary policy rule (11), this procedure yields a system of three equations that can be solved each period to obtain the three realizations $y_t$, $\pi_t$, and $i_t^*$.

The decision rule coefficients applied to the state variable $r_t - E_t r_t^*$ are much larger in magnitude in the deflation equilibrium than in the targeted equilibrium (see Appendices B and C). Consequently, the deflation equilibrium exhibits more volatility and undergoes a more severe recession in response to an adverse shock sequence that causes $r_t - E_t r_t^*$ to be persistently negative. The higher volatility in the deflation equilibrium is due to the binding ZLB which prevents the central bank from taking action to mitigate the consequences of the adverse shock sequence.

The local linear forecast rules for the targeted equilibrium are derived under the assumption that $i_t^* > 0$ and hence do not take into account the possibility that a shock sequence could be large enough to cause the ZLB to become binding in the future. The error induced by the use of linear forecast rules will depend on the frequency and duration of ZLB episodes in the targeted equilibrium. Based on model simulations, the targeted equilibrium experiences a binding ZLB in only 2.5% of the periods, with an average duration of 5.3 quarters. The local linear forecast rules for the deflation equilibrium are derived under the assumption that $i_t^* \leq 0$ and hence do not take into account the possibility that a shock sequence could be large enough to cause the ZLB to become slack in the future. Based on model simulations, the deflation equilibrium

\(^{15}\)For background on MSV solutions, see McCallum (1999).
experiences a binding ZLB in 80% of the periods, with an average duration of 35 quarters. The average duration of a slack ZLB episode in the deflation equilibrium is 8.5 quarters. It is important to recognize, however, that the agent in the switching model (described below) does not encounter these particular statistics because they pertain to environments with no regime switching. In Section 4, I show that the agent’s forecast errors in the switching model are close to white noise.

Aruoba, Cuba-Borda, and Schorfheide (2018) solve for piece-wise linear decision rules to account for the occasionally binding nature of the ZLB constraint within each of the two regimes of their model. They report (p. 104), that the probability of hitting the ZLB in the targeted-inflation regime is “virtually zero” given the pre-crisis distribution of shocks. In the deflation regime, the probability of hitting the ZLB is 89%. These statistics are similar to those obtained here using the linear forecast rules.

Focusing only on the targeted equilibrium, Richter and Throckmorton (2016) compare a linear model solution in which agents’ forecasts do not account for the possibility of hitting the ZLB (but the ZLB is imposed in simulations, as done here) to a nonlinear model solution in which agents’ forecasts do account for this possibility. They report that the posterior distributions and marginal likelihoods of the two models are similar. But the nonlinear model predicts higher output volatility and more-negative skewness in output and inflation during the ZLB episode.

2.3 Endogenous regime switching

I now consider an agent who contemplates the possibility of an occasionally binding ZLB that is driven by switching between the two local equilibria, which can be viewed as two separate regimes. This setup bears some resemblance to the “OccBin toolkit” solution method developed by Guerrieri and Iacoviello (2015). Despite taking into account the possibility of occasionally hitting the ZLB, the agent’s use of linear forecast rules within each regime is fully rational only in a vicinity of the model’s long-run endpoints.

From the agent’s perspective, one set of local linear forecast rules might perform better than the other depending on the realizations of the macroeconomic variables over a given sample period. The agent constructs forecasts using a form of model averaging—a technique that is often employed to improve forecast performance in situations where the true data generating process (or true regime) is unknown (Timmerman 2006). The agent in the switching model can be viewed as an econometrician trying to identify the best forecast rule for the environment.
Along the lines of Bullard (2010), the agent is aware of the two local equilibria implied by the economic framework and is concerned about the possibility of getting stuck in a deflation trap. The forecast rules in the switching model are given by

\[ \begin{align*}
\tilde{E}_t y_{t+1} &= \mu_t E_t^{\text{target}} y_{t+1} + (1 - \mu_t) E_t^{\text{defl}} y_{t+1}, \\
\tilde{E}_t \pi_{t+1} &= \mu_t E_t^{\text{target}} \pi_{t+1} + (1 - \mu_t) E_t^{\text{defl}} \pi_{t+1},
\end{align*} \]

where \( \mu_t \) is the value that minimizes the root mean squared forecast error computed over a moving window of recent data. Specifically, \( \mu_t \) is the value that minimizes:

\[ R\text{MSFE}_{t-1} = \sum_{j=1}^{T_w} \left\{ \frac{1}{T_w} \left[ y_{t-j} - \mu_t E_{t-j-1}^{\text{target}} y_{t-j} - (1 - \mu_t) E_{t-j-1}^{\text{defl}} y_{t-j} \right]^2 + \frac{1}{T_w} \left[ \pi_{t-j} - \mu_t E_{t-j-1}^{\text{target}} \pi_{t-j} - (1 - \mu_t) E_{t-j-1}^{\text{defl}} \pi_{t-j} \right]^2 \right\}^{0.5}, \]

which shows that \( \mu_t \) is computed using data dated \( t - 1 \) or earlier. In the simulations, I impose the restriction \( 0 \leq \mu_t \leq 1 \).

I show that similar results are obtained if \( \mu_t \) is determined by a logistic rule that is formulated along the lines recommended by Binning and Maih (2017) for solving models with occasionally-binding constraints. The logistic rule takes the form:

\[ \mu_t = \frac{\exp(\psi i_{t-1}^*)}{1 + \exp(\psi i_{t-1}^*)}, \]

where \( \psi > 0 \) is a parameter. The logistic rule implies that \( \mu_t \) will decline when the desired nominal policy rate approaches zero or crosses into negative territory. As \( \psi \) becomes larger, the resulting sequence for \( \mu_t \) takes on values approaching either 1 or 0, with intermediate values less likely.

Given the representative agent’s conditional forecasts from equations (14) and (15), the realizations of the endogenous macroeconomic variables \( y_t, \pi_t, i_t^* \) and \( i_t \) are determined simultaneously each period by solving the following nonlinear system of equations:

\[ \begin{align*}
y_t &= \tilde{E}_t y_{t+1} - \alpha \left[ i_t - \tilde{E}_t \pi_{t+1} - \tau_t \right] + \nu_t, \\
\pi_t &= \beta \tilde{E}_t \pi_{t+1} + \kappa y_t + u_t, \\
i_t^* &= \rho i_{t-1}^* + (1 - \rho) \left[ E_t r_t^* + \pi^* + g(\pi_t - \pi^*) + g(y_t - y^*) \right], \\
i_t &= 0.5 i_t^* + 0.5 \sqrt{(i_t^*)^2},
\end{align*} \]

where \( \bar{\pi}_t = \omega \pi_t + (1 - \omega) \bar{\pi}_{t-1} \).
3 Parameter values

Table 2 shows the baseline parameter values used in the model simulations. The top group of parameters appear in the private-sector equilibrium conditions (1) and (2). The middle group of parameters appear in the monetary policy rule (11). The bottom group of parameters pertain to the exogenous real interest rate process and the forecast evaluation window for the switching model.

</table>

The value $\alpha = 0.15$ for the interest rate sensitivity coefficient in equation (1) implies a coefficient of relative risk aversion of $1/\alpha \approx 6.7$. This value is consistent with the small empirical sensitivity of consumption to changes in the interest rate, as shown originally by Campbell and Mankiw (1989). The Phillips curve parameters $\beta = 0.995$ and $\kappa = 0.025$ are identical to those employed by Evans et al. (2015) and are typical of values employed in the literature. The parameters that govern the aggregate demand shock in equation (3) and the cost push shock in equation (4) are computed from a quantitative exercise (described in section 4.3) in which I solve for the time series $\nu_t$ and $u_t$ that allow the switching model to exactly replicate the observed time paths of the CBO output gap, quarterly PCE inflation, and the federal funds rate since 1988.

The inflation target of $\pi^* = 0.02$ is based on the Federal Open Market Committee's (FOMC) stated goal of 2% inflation, as measured by the 4-quarter change in the personal
consumption expenditures (PCE) price index. I choose $\omega = 0.459$ to minimize the squared deviation between the 4-quarter PCE inflation rate and the exponentially-weighted moving average of quarterly PCE inflation computed using equation (12) for the period 1961.Q1 to 2017.Q2. When $\omega = 0.459$, the cumulative weight in the moving average on the first four terms $\pi_t$ through $\pi_{t-3}$ is 0.915. The monetary policy rule coefficients $g_\pi$, $g_y$ and $\rho$ are based on the Taylor (1999) rule, augmented to allow for a realistic amount of inertia in the desired nominal policy rate.

The parameter values that govern the evolution of $r_t$ and $r_t^*$ in equations (5) and (6) are calibrated so that the Kalman filter estimate $E_t r_t^*$ computed from equation (9) approximates the one-sided Laubach-Williams estimate of the natural rate for the period 1988.Q1 to 2017.Q2. Similar results are obtained if parameters are chosen to approximate an alternative natural rate series estimated by Lubik and Matthes (2015). Given the considerable uncertainty surrounding estimates of $r_t^*$, any observed differences between the two series are not statistically significant.\(^\text{16}\)

As is common in the literature, the model variable $r_t$ is considered observable. This raises the question of what observable data should be used to represent $r_t$ for model calibration purposes? A candidate series for $r_t$ is constructed as the nominal federal funds rate minus expected quarterly inflation computed from a rolling 40-quarter, 4-lag vector autoregression that includes the nominal funds rate, quarterly PCE inflation (annualized), and the CBO output gap. The resulting series, plotted in Figure 1, is labeled as the “real federal funds rate.” An alternative series for $r_t$ might be the “efficient real rate” constructed by Curdia et al. (2015) to represent the real interest rate that would prevail if the economy were perfectly competitive. But since the actual economy is not perfectly competitive, the efficient real rate may be more difficult to observe. Figure 1 shows that the two candidate series for $r_t$ exhibit similar behavior since 1988. The correlation coefficient between the series is 0.83. Moreover, any differences between the two series are unlikely to be statistically significant. For calibration purposes, I use real federal funds rate to represent $r_t$.

Equation (5) implies $E_t r_{t+1} = \rho_r r_t + (1 - \rho_r) E_t r_t^*$. I choose $\rho_r = 0.8564$ to minimize the squared forecast error $[r_{t+1} - \rho_r r_t - (1 - \rho_r) E_t r_t^*]^2$ over the period 1988.Q1 to 2016.Q4, where $r_t$ is the real federal funds rate and $E_t r_t^*$ is the Laubach-Williams one-sided estimate. Given the value of $\rho_r$, I choose $\lambda = 0.0257$ to minimize the squared deviations between the model-implied estimate $E_t r_t^*$ from equation (9) and the Laubach-Williams estimate. Given

\(^{16}\text{According to Kiley (2015, p. 2), “the co-movement of output, inflation, unemployment, and real interest rates is too weak to yield precise estimates of } r^*.”\)
these values for $\rho_t$ and $\lambda$, I solve for the value $\phi = \sigma_\eta^2 / \sigma_\varepsilon^2 = 0.033$ to satisfy the optimal Kalman gain formula (10). Given $\phi$, I solve for the value of $\sigma_\varepsilon$ that allows the model-predicted standard deviation of $\Delta r_t$ to match the corresponding value in the data for the period 1988.Q1 to 2017.Q2. Finally, given $\phi$ and $\sigma_\varepsilon$, we have $\sigma_\eta = \sigma_\varepsilon \sqrt{\phi}$.

The window length in quarters for computing the agent’s forecast fitness measure from equation (16) is set to $T_w = 8$. Each period, the agent chooses the weight $\mu_t$ on the targeted forecast rules so as to minimize the root mean squared forecast errors over the past 2 years. In simulations, this choice produces a ZLB binding frequency of around 20%—reasonably close to the frequency observed in U.S. data since 1988. I also examine the sensitivity of the results to higher values of $T_w$. Higher values of $T_w$ serve to reduce the ZLB binding frequency by reducing the likelihood of switches to the deflation equilibrium.

Figure 3 plots the one-sided Laubach-Williams estimate of the natural rate through 2017.Q2. The series (dashed red line) shows a downward-sloping trend. This pattern is consistent with the declines in global real interest rates observed over the same period (International Monetary Fund 2014, Rachel and Smith 2017). The time series process for the natural rate in the model (dotted green line) provides a good approximation of the Laubach-Williams series from 1988 onwards. Table 3 compares the properties of the real federal funds rate to $r_t$ in the model.

Notes: $\Delta r_t \equiv r_t - r_{t-1}$, $\Delta^2 r_t \equiv \Delta r_t - \Delta r_{t-1}$. The time series for $r_t$ in the data is constructed as the nominal federal funds rate minus expected quarterly inflation computed from a rolling 40-quarter, 4-lag vector autoregression that includes the nominal funds rate, quarterly PCE inflation, and the CBO output gap. The Kalman filter estimate $\hat{E}_t r_t^*$ in U.S. data corresponds to the Laubach-Williams one-sided estimate. Model statistics are computed analytically from the laws of motion (5), (6), and (9).

For the baseline simulation, I impose the bounds $-0.0039 \leq r_t^* \leq 0.037$, which corresponds to the range of values for the Laubach-Williams one-sided estimate since 1988. But this approach involves additional parameters and presumes that the agent has prior knowledge of the upper and lower bounds on $r_t^*$.

Alternatively, one could model $r_t^*$ as a “bounded random walk” along the lines described by Nicolau (2002).
bound of 1.5% is the long-run value of the natural rate of interest computed by Eggertsson, Mehrotra, and Robbins (2017) using a life cycle model calibrated to the U.S. economy in 2015.

In a representative agent model, the long-run natural rate influences the mean real risk free rate of return. The mean risk free rate can be negative if the product of the coefficient of relative risk aversion and the variance of consumption growth are sufficiently high, implying a very strong precautionary saving motive.18

4 Quantitative analysis

4.1 U.S. data around the ZLB episode

The top left panel of Figure 4 shows that the real federal funds rate has remained mostly below the Laubach-Williams estimate of the natural rate of interest since early 2009, implying persistently negative values for the real rate gap \( r_t - E_t r_t^* \), which is a state variable in the model. The bottom left panel shows that the nominal federal funds rate was approximately zero from 2008.Q4 through 2015.Q4. In the same panel, I plot the nominal federal funds rate predicted by a Taylor-type rule of the form (11) using the parameter values in Table 2 with \( E_t r_t^* \) given by Laubach-Williams one-sided estimate, \( \pi_t \) given by the 4-quarter PCE inflation rate, and \( y_t \) given by the CBO output gap. The desired nominal funds rate predicted by the Taylor-type rule is negative starting in 2009.Q1 and remains negative through 2016.Q4.19

The top right panel of Figure 4 shows that the 4-quarter PCE inflation rate was briefly negative in 2009 and has remained below the Fed’s 2% inflation target since 2012.Q2. The bottom right panel shows that the Great Recession was very severe, pushing the CBO output gap down to −6.3% at the business cycle trough in 2009.Q2. This was the most severe economic contraction since 1947 as measured by the peak-to-trough decline in real GDP. The output gap remains negative at −0.2% in 2017.Q2, eight years after the Great Recession ended.

The various endpoints plotted in Figure 4 are computed using the expressions in Table 1, with \( r_t^* \) given by the Laubach-Williams one-sided estimate. Although not shown, the wide confidence intervals surrounding empirical estimates of \( r_t^* \) would not rule out values for the

18In a representative agent model, \( \log(R_{t+1}^f) = -\log(E_t M_{t+1}) \), where \( R_{t+1}^f \) is the gross real risk free rate and \( M_{t+1} \) is the agent’s stochastic discount factor. Assuming iid consumption growth and power utility, the mean risk free rate is given by \( E[\log(R_{t+1}^f)] = -\log(\beta) + \gamma \pi - \gamma^2 \sigma_x^2 / 2 \), where \( \beta \) is the agent’s time discount factor, \( \gamma \) is the coefficient of relative risk aversion, \( \pi \) is the mean growth rate of real per capita consumption and \( \sigma_x^2 \) is the corresponding variance. Assuming \( \beta \approx 1 \) such that \( \log(\beta) \approx 0 \), the condition \( \gamma \sigma_x^2 > 2 \pi \) implies \( E[\log(R_{t+1}^f)] < 0 \). For details of the derivation, see Lansing and LeRoy (2014).

19Augmenting the Taylor-type rule to allow for a response to other variables (such as 4-quarter real GDP growth and an index of macroeconomic uncertainty) can produce a path for the desired nominal funds rate that turns positive somewhat earlier. See Lansing (2017).
true natural rate that lie deeper in negative territory. As $r^*_t$ approaches zero or becomes negative, the “deflation” equilibrium is characterized by zero or low inflation, allowing this equilibrium to provide a better fit of recent U.S. inflation data. Aruoba, Cuba-Borda, and Schorfheide (2018) impose a relatively low value of $r^* = 0.86\%$, but they do not allow its value to vary over time.

### 4.2 Expected inflation in U.S. data

Figure 5 plots various measures of expected inflation in U.S. data. The top right panel shows 1-year and 5-year expected inflation rates derived from zero coupon inflation swap contracts that are traded in the over-the-counter market (Haubrich, Pennacchi, and Ritchken 2012). Expected inflation dropped sharply in 2008.Q4, coinciding with the start of the ZLB episode. In the top right panel, we see a similar pattern for 5-year and 10-year breakeven inflation rates derived from yields on Treasury Inflation Protected Securities (TIPS). All of the market-based measures of expected inflation remain below the Fed’s 2% inflation target at the end of the data sample in 2017.Q2. The lower left panel in Figure 5 shows the median 1-year and 10-year expected inflation rates from the Survey of Professional Forecasters (SPF). The 1-year survey measure dropped sharply in 2008.Q4 and has recovered slowly, but to a level that remains below its pre-recession range. The 10-year survey measure does not exhibit a sharp drop in 2008.Q4, but has since trended downward to a level that is below its pre-recession range. The bottom right panel plots the Federal Reserve Bank of St. Louis’ Price Pressures Measure (PPM). A set of common factors extracted from 104 separate data series are used to estimate the probability that the 4-quarter PCE inflation rate over the next year will exceed 2.5% (Jackson, Kliesen, and Owyang 2015). The PPM dropped sharply in 2008.Q4 and is currently hovering around a probability of 10%.

Aruoba and Schorfheide (2016, p. 363) claim that “long-run (five-year-ahead) inflation expectations have been remarkably stable in the United States... despite falling policy rates.” However, they do not consider the market-based measures of expected inflation shown in the top panels of Figure 5. Although not plotted in Figure 5, the Federal Reserve Bank of Atlanta’s Business Inflation Expectation (BIE) survey shows that while most respondents understand that the Fed’s inflation target is 2%, about two-fifths of respondents currently believe that the Fed is more likely to accept an inflation rate below target than to accept an inflation rate below target.

---

20The TIPS breakeven inflation rates and the PPM are from the Federal Reserve Bank of St. Louis’ FRED database. Expected inflation rates from swap contracts are from the Federal Reserve Bank of Cleveland. Expected inflation rates from the SPF are from the Federal Reserve Bank of Philadelphia.
above target (Altig, Parker, and Meyer, 2017).

4.3 Replicating U.S. data since 1988 with the switching model

Given the U.S. data counterparts for the model variables $i_t$, $r_t$, $E_t r^*_t$, $y_t$, $\pi_t$, $\pi_t \approx \pi_{4,t}$, and $i_t^*$ (as plotted in Figure 4), we can use the calibrated switching model to “reverse engineer” the time series of the two persistent shocks $\nu_t$ and $u_t$ that are needed to exactly replicate the data.\(^\text{21}\) For this computation, the agent’s subjective forecasts $\hat{E}_t y_{t+1}$ and $\hat{E}_t \pi_{t+1}$ that appear in the equilibrium conditions (18) and (19) are constructed as the weighted averages shown in equations (14) and (15), with U.S. data inserted for the state variables that appear in the two sets of local linear forecast rules. The variable $i_t$ is the nominal federal funds rate, $r_t - E_t r^*_t$ is the difference between the real federal funds rate and the Laubach-Williams one-sided estimate of the natural rate of interest, $y_t$ is the CBO output gap, $\pi_t$ is quarterly PCE inflation, and $\pi_t$ is 4-quarter PCE inflation. During the ZLB episode in the data, $i_t^*$ is given by the calibrated policy rule (11). Otherwise, $i_t^* = i_t$. The forecast weight $\mu_t$ is computed each period so as to minimize the $RMSFE$ from equation (16), where $T_w = 8$ quarters. The shock persistence parameters $\rho_{\nu}$ and $\rho_{u}$ can influence the values of the coefficients in the local linear forecast rules. I start with guesses for $\rho_{\nu}$ and $\rho_{u}$ and then repeat the exercise until convergence. The converged shock parameters are shown Table 1. The results of the data replication exercise are plotted in Figure 6.

The top left panel of Figure 6 shows the model-implied shocks $\nu_t$ and $u_t$. Both shocks become strongly negative at the start of the ZLB episode in 2008.Q4. These adverse shock sequences allow the model to exactly replicate the sharp drops in the CBO output gap and quarterly PCE inflation shown earlier in Figure 4. The standard deviations of $\nu_t$ and $u_t$ are about 0.005 and 0.01, respectively, with $\rho_{\nu} = 0.8$ and $\rho_{u} = 0.3$.

The top right panel of Figure 6 compares the $RMSFE$ of the deflation forecast rules to the $RMSFE$ of the targeted forecast rules. The performance gap between the two sets of forecast rules starts to narrow considerably after 2008.Q4. The weight $\mu_t$ on the targeted forecast rules drops sharply during the Great Recession, but then declines more gradually afterwards, eventually reaching a minimum value of 0.43 in 2016.Q4 (bottom right panel). The deflation forecast rules start to slightly outperform the targeted forecast rules in 2014.Q2. At the end of the data sample, the value of $\mu_t$ is 0.56, helping the switching model to account for the persistent undershooting of the Fed’s 2% inflation target since mid-2012.

\(^{21}\)Gelain, Lansing, and Natvik (2018) undertake a similar reverse-engineering exercise to identify the shocks needed to exactly replicate housing market data from 1993 onwards.
The bottom left panel of Figure 6 compares the 1-year expected inflation rate from U.S. inflation swaps (shown earlier in Figure 5) to the path of \( \hat{E}_t \pi_{t+1} \) from the switching model. The correlation coefficient between the two series is 0.81. While the model-implied drop in expected inflation is somewhat more pronounced and more persistent than in the data, both series remain below the Fed’s 2% inflation target at the end of the data sample in 2017.Q2. Due to the persistent nature of the shocks, the agent’s subjective forecast \( \hat{E}_t \pi_{t+1} \) makes use of the identified shocks \( \nu_t \) and \( u_t \). These same shock values allow the switching model to exactly replicate the path of \( \pi_t \) in the data.

Of course, one could solve for different sequences of \( \nu_t \) and \( u_t \) that would allow the targeted equilibrium with \( \mu_t = 1 \) for all \( t \), or the deflation equilibrium with \( \mu_t = 0 \) for all \( t \), to similarly replicate the U.S. data. But the RMSFE minimization procedure employed by the agent in the model prefers interior solutions with \( 0 < \mu_t < 1 \). Since \( \mu_t \) is endogenous, the switching model provides us with an economic rationale for why measures of actual and expected U.S. inflation in the data have mostly not returned to their pre-recession levels.

Can the results of the data replication exercise be reconciled with those of Arouba, Cuba-Borda, and Schorfheide (2018), henceforth ACS? Possibly so. Recall that ACS conclude that “the U.S. remained in the targeted-inflation regime during its ZLB episode, with the possible exception of the early part of 2009 where evidence is ambiguous.” First, we should recognize that ACS compare the likelihood of the targeted-inflation regime to the likelihood of the deflation regime. According to their model, the economy must be in one regime or the other. In contrast, the data replication exercise tells us that the data since 2008.Q4 are best described as a mixture of the two regimes with \( 0 < \mu_t < 1 \). ACS do not consider the possibility of a mixed regime. Second, while ACS explicitly consider model uncertainty, a number of their model parameters are fixed during the estimation routine. The most notable of these is the natural rate of interest which is held constant at 0.86%. The uncertainty surrounding point estimates of the natural rate is extremely large (Kiley 2015). It could easily be the case that the true value of the steady state natural rate lies in negative territory, as maintained by Eggertsson, Mehrotra, and Robbins (2017). When the natural rate is negative, the “deflation” equilibrium is characterized by positive inflation, allowing this equilibrium to provide a better fit of recent U.S. inflation data. The upshot of these points is that the conclusions of ACS may not be robust to realistic alternative environments.
4.4 Switching model simulations

Numerical simulations can provide further insight into the behavior of the switching model. Figure 7 plots some key variables from a long simulation using the parameter values in Table 1. When the exogenous real interest rate gap \( r_t - E_t r^*_t \) is negative for a sustained interval (top panel), the resulting downward pressure on \( y_t \) and \( \pi_t \) serves to reduce the recent RMSFE of the deflation forecast rules and increase the recent RMSFE of the targeted forecast rules (middle panel). Around period 1725, the shift in relative forecast performance induces the agent to reduce the weight on the targeted forecast rules. The lower weight puts further downward pressure on \( y_t \) and \( \pi_t \), causing the deflation equilibrium to eventually become fully realized around period 1750 (bottom panel). Then around period 1800, the real rate gap once again becomes positive, putting upward pressure on \( y_t \) and \( \pi_t \). The RMSFE of the deflation forecast rules starts to exceed the RMSFE of the targeted forecast rules. The agent increases the weight on the targeted forecast rules which puts further upward pressure on \( y_t \) and \( \pi_t \), eventually causing the targeted equilibrium to be restored.

Around period 1610, the switching model produces an episode where the ZLB is binding for an extended period, but \( 0.6 \lesssim \mu_t \lesssim 0.8 \). In this case, the model-generated data are a mixture of the two local equilibria, similar to results obtained in the U.S. data replication exercise.

Qualitatively similar results are obtained if the agent employs the logistic rule (17) to compute the forecast weight each period. The bottom panel of Figure 7 shows the path of \( \mu_t \) that is implied by the logistic rule with \( \psi = 2000 \), corresponding to the value employed by Binning and Maih (2017) in a similar modeling context. Interestingly, it is the agent’s subjective belief that the deflation equilibrium is possible that allows it to become a reality. If the agent could somehow commit to employing the forecast rule weight \( \mu_t = 1 \) for all \( t \), then the economy would always remain in the targeted equilibrium.

Figure 8 plots the distributions of macro variables in each of the three model versions. The macro variables in the deflation equilibrium have distributions with lower means but higher variances than those in the targeted equilibrium. But the significant overlap in the various distributions creates a dilemma for an agent who seeks to determine the likelihood that a string of recent data observations are generated by one equilibrium or the other. Variables in the switching model have means that are somewhat lower and variances that are somewhat higher than those in the targeted equilibrium. Consequently, the central bank in the switching model undershoots its inflation target and the volatilities of the output gap and inflation are both higher relative to the targeted equilibrium.
Hills, Nakata, and Schmidt (2016) show that the risk of encountering the ZLB in the future can shift agents' expectations such that the central bank undershoots its inflation target in the present. Something similar is at work here. When the agent increases the weight on the deflation forecast rules, this can cause realized inflation to undershoot the central bank’s target for a sustained interval, even when the ZLB is not binding. The switching model allows for low-frequency swings in the level of inflation that are driven solely by expectational feedback, not by changes in the monetary policy rule.\(^{22}\)

As mentioned above, the U.S. output gap reached \(-6.3\%\) at the trough of the Great Recession. The bottom right panel of Figure 8 shows that the likelihood of such an event in the targeted equilibrium is essentially zero. In contrast, a Great Recession-type episode is plausible, albeit rare, in the switching model.

Notes: The ZLB episode in U.S. data is from 2008.Q4 through 2015.Q4. Model results are computed from a 300,000 period simulation. \(\pi_{4,t} \equiv [\Pi_{j=0}^{3}(1 + \pi_{t-j})]^{0.25} - 1\).

Table 4 provides a quantitative comparison between the U.S. data and the results of model simulations. Overall, the statistics generated by the switching model compare favorably to those in U.S. data since 1988. For example, the switching model predicts a ZLB binding frequency of 19.6\% versus 24.6\% in the data. However, the mean 4-quarter inflation rate in the switching model is only 0.93\% versus 2.16\% in the data. This particular model prediction is more in line with data from Japan than the United States. But as shown later in Table 6, \(^{22}\) Lansing (2009) achieves a similar result in a model where the representative agent’s forecast rule for quarterly inflation is based on a perceived law of motion that follows a Stock and Watson (2007) type time series process.
the mean 4-quarter inflation rate in the switching model can be increased by allowing $r_t^*$ to
dip further into negative territory during the simulations.

Using data from all advanced economies since 1950, Dordal-i-Carrera et al. (2016) estimate
an average ZLB binding frequency of 7.5% and an average duration for ZLB episodes of 14
quarters. Excluding the high inflation period from 1968 to 1984 serves to raise the average
ZLB binding frequency and the average ZLB duration to 10% and 18 quarters, respectively.
For the period of consistent U.S. monetary policy since 1988, the single ZLB episode lasted
29 quarters.

Figure 9 plots the distribution of ZLB durations in each model version. Unlike the tar-
geted equilibrium, the switching model can produce infrequent and long-lived ZLB episodes
in response to small, normally distributed shocks. The average ZLB duration in the switching
model is 12.5 quarters, with a maximum observed duration in the simulation of 133 quarters
(Table 4). From Figure 9, we see that a 29 quarter ZLB episode is an extremely rare event
in the targeted equilibrium but can occur with about 5% frequency in the switching model.
To account for infrequent and long-lived ZLB episodes in the targeted equilibrium, Dordal-i-
Carreras, et al. (2016) develop a model with large, infrequent, and long-lived shocks.23

When $\omega = 0.459$, the exponentially-weighted moving average of quarterly inflation $\pi_t$ com-
puted from equation (13) provides a very good approximation of the 4-quarter inflation rate.
Although not shown in Table 4, the mean, standard deviation, and first-order autocorrelation
of $\pi_t$ in the switching model are 0.94%, 1.48%, and 0.90, respectively. These values are close
to the corresponding statistics for $\pi_{4,t}$ of 0.93%, 1.46%, and 0.95.

The mean weight on the targeted forecast rules in the switching model is 0.69 with a
standard deviation of 0.29. Larger values for the window length $T_w$ that is used to compute
the $RMSFE$ measure from equation (16) serve to reduce the frequency of regime switches
and thereby raise the mean 4-quarter inflation rate. For example, when $T_w$ is increased to 16
quarters, the mean value of $\mu_t$ is higher at 0.78 and the standard deviation is lower at 0.22.
With $T_w = 16$, the ZLB binding frequency in the switching model drops to 12.3% and the
average ZLB duration is lower at 9.2 quarters. The mean value of $\pi_{4,t}$ increases to 1.24% from
0.93%.

Figure 10 plots simulations from each of the three model versions: targeted, deflation,
and switching. All three versions employ the same sequence of stochastic shocks. When the
weight on the targeted forecast rules starts dropping around period 1725, the switching model

---

23 In a New Keynesian model with physical capital, Dennis (2016) shows that the introduction of capital
adjustment costs can help to generate infrequent and long-lived ZLB episodes in the targeted equilibrium.
generates a negative desired nominal policy rate, a binding ZLB, brief deflation followed by
below-target inflation, and a highly negative output gap, reminiscent of the U.S. Great Reces-
sion and its aftermath (Figure 4). The severity of the recession in the switching model is due
to the larger response coefficients on the state variables $r_t - E_t r_t^*$ and $\nu_t$ in the deflation equi-
librium decision rule for $y_t$. Specifically, the response coefficient on $r_t - E_t r_t^*$ in the deflation
equilibrium is 1.25 versus 0.59 in the targeted equilibrium. The corresponding response coef-
ficients on $\nu_t$ are 5.40 versus 3.22 (Appendices B and C). The deflation equilibrium response
coefficients have more influence as the forecast weight $\mu_t$ declines, causing adverse realizations
of $r_t - E_t r_t^*$ or $\nu_t$ to be transmitted more forcefully to the output gap.

Evans, Honkapohja, and Mitra (2016) argue that the deflation equilibrium does not provide
a convincing explanation of the sluggish output recovery following the Great Recession because
the steady state level of real activity in the deflation equilibrium is not much below the steady
state level of real activity in the targeted equilibrium. However, their analysis does not take
into account that the real rate gap $r_t - E_t r_t^*$ in U.S. data has remained significantly negative
since the recession ended, as can be seen in the top left panel of Figure 4. A negative real
rate gap puts stronger downward pressure on $y_t$ in the deflation equilibrium, thus helping
to explain the sluggish output recovery in U.S. data. Moreover, as we saw from the data
replication exercise, putting some weight on the deflation equilibrium forecast rules can help
to explain the pattern of U.S. data, even if the deflation equilibrium is never fully realized.

As noted earlier, the agent in the switching model considers the ZLB to be occasionally
binding across regimes, but not within a given regime. Most of the time, the switching model
fluctuates in a state that can be described as a mixture of the two regimes. Each period, the
agent adjusts the forecast weight $\mu_t$ in a way that is perceived to improve forecast accuracy.
In such an environment, the agent’s failure to take into account a relatively rare within-regime
event should not have much impact on overall forecasting performance. Table 5 summarizes
the properties of the agent’s forecast errors in each of the three model versions. The forecast
error is given by $err_{t+1} = x_{t+1} - F_t x_{t+1}$ for $x_{t+1} \in \{y_{t+1}, \pi_{t+1}\}$, where $F_t x_{t+1}$ is the value
predicted by the local linear forecast rule or, in the case of the switching model, the weighted-
average forecast rule, (14) or (15). The properties of the agent’s forecast errors in the switching
model are not much different from those in the targeted equilibrium. Notably, the forecast
errors are close to white noise.

Notes: Model results are computed from a 300,000 period simulation.

Recall that the long-run endpoint of $\pi_t$ in the deflation equilibrium is $-r_t^*$. Allowing more negative values of $r_t^*$ in the simulation will therefore serve to increase the mean inflation rate in both the deflation equilibrium and the switching model. In Figure 7, for example, the real rate gap $r_t - E_t r_t^*$ becomes positive around period 1800 because $E_t r_t^*$ becomes negative. At the same time, Figure 10 shows that the 4-quarter inflation rate in the deflation equilibrium becomes positive. The wide confidence intervals around empirical estimates of the natural rate of interest would not rule out true values that are more negative. To explore this idea further, the simulations are repeated while imposing the wider bounds $-0.015 \leq r_t^* \leq 0.037$, where the lower bound of $-1.5\%$ is the long-run value of the natural rate of interest computed by Eggertsson, Mehrotra, and Robbins (2017) using a life cycle model calibrated to the U.S. economy in 2015.

Table 6 compares the results of the original switching model simulation to an alternative simulation with $-0.015 \leq r_t^* \leq 0.037$, thus allowing $r_t^*$ to dip further into negative territory. The mean 4-quarter inflation rate in the alternative simulation increases to 1.08% from 0.93% in the original simulation. Moreover, the ZLB binding frequency increases to 23.2%, which is closer to the U.S. data value of 24.6% shown in Table 4. The last column of Table 6 shows the results of imposing a constant natural rate of interest with $r^* = 0.86\%$, corresponding to the value employed by Aruoba, Cuba-Borda, and Schorfheide (2018). The results with constant $r^*$ are broadly similar to the original switching model simulation, with the exception that the mean value of $i_t^*$ is now quite low at 1.47%. The corresponding value in U.S. data from Table 4 is 2.83%.

4.5 Effect of raising the inflation target

In a press conference held on June 14, 2017, Fed Chair Janet Yellen stated that determining the appropriate level of the inflation target “is one of the most important questions facing monetary policy around the world in the future.” Numerous authors make the case for a higher inflation target using frameworks that ignore the deflation equilibrium. This methodology may understate the benefits of a higher inflation target because the analysis does not take into account the possibility that a higher target could help prevent switching to the volatile deflation equilibrium where recessions are more severe. Aruoba and Schorfheide (2016) consider the welfare implications of a 4% inflation target in a framework that does consider the possibility of switching to the deflation equilibrium via an exogenous sunspot shock. They conclude (p. 395) that “the case for a higher inflation target is not particularly strong.” It’s worth noting, however, that the probability of switching to the deflation equilibrium in the Aruoba-Schorfheide model is invariant to changes in the inflation target. In contrast, the framework developed here has the potential to reduce the probability of switching to the deflation equilibrium. This potential benefit should be considered as part of any cost-benefit analysis of a higher inflation target.

Table 7 shows the effects of raising the central bank’s inflation target. As $\pi^*$ increases, the ZLB binding frequency declines as does the mean duration of ZLB episodes. Higher values of $\pi^*$ serve to reduce the volatility of $y_t$ because the volatile deflation equilibrium is now avoided more often. But at the same time, higher values of $\pi^*$ serve to increase the volatility of $y_{4,t}.$

24See, for example, Blanchard, Dell’Ariccia, and Mauro (2010), Ball and Mazumder (2011), and Ball (2013).
This is because higher values of \( \pi^* \) widen the spread between the two inflation distributions implied by the the two local equilibria. This causes the mean inflation rate to shift by a larger amount when a regime switch inevitably does occur.

From Table 7 we see that an increase in \( \pi^* \) can reduce, but not eliminate, the endogenous switches to the deflation equilibrium. Even with an inflation target of 4\%, the ZLB binding frequency remains relatively high at 9.5\%, the average duration of a ZLB episode is 11.7 quarters, and the maximum observed duration in the simulation is 165 quarters, or about 41 years. Once the possibility of switching to the deflation equilibrium is taken into account, raising the inflation target is a less effective solution for avoiding long-lived ZLB episodes.

Note: Model results computed from a 300,000 period simulation. \( \pi_{4,t} \equiv \left[ \prod_{j=0}^{t} (1 + \pi_{t-j}) \right]^{0.25} - 1. \)

Coibion, Gorodnichenko, and Wieland (2012) calibrate their model to deliver a ZLB binding frequency equal to that observed in U.S. data going back to the year 1950. From the start of 1950 to 2017.Q2, the ZLB was binding in 29 out of 270 quarters, or 10.7\% of the time. The average CPI inflation rate in U.S. data since 1950 is around 4\%. Table 7 shows that the switching model with \( \pi^* = 0.04 \) delivers a ZLB binding frequency of 9.5\%—reasonably close to the U.S. value of 10.7\% going back to 1950. Taking into account the micro-founded welfare costs of positive and variable inflation, Coibion, Gorodnichenko, and Wieland (2012) compute an optimal inflation rate for their model which is relatively low, less than 2\% per year. Their analysis is extended by Dordal-i-Carrera et al. (2016), who modify the shock process in the model to match the now-higher ZLB binding frequency implied by additional years of data for the U.S. and other advanced economies. The optimal inflation rate for the modified model lies in the range of 2.5\% to 4\%.

Kiley and Roberts (2017) perform stochastic simulations using the DSGE model of Lindé, Smets, and Wouters (2016) which is estimated over the period 1965.Q1 to 2014.Q2. They consider constant values of the natural rate of interest as low as 1\% and draws shocks from
the estimated distributions of the model. When monetary policy follows a simple Taylor (1999) rule with no interest rate smoothing, they find that the ZLB binding frequency can be as high as 32.6% with an mean ZLB duration of 12 quarters. The very high ZLB binding frequency obtains even though the model solution considers only the targeted equilibrium. In contrast, the simulations here deliver a baseline ZLB binding frequency in the switching model of 19.6%, despite allowing for a natural rate of interest as low as \(-0.39\%\) and further allowing for the possibility of switches to the deflation equilibrium. The much higher ZLB binding frequency obtained by Kiley and Roberts (2017) appears to be partly due to the shock distributions which are based on the more-volatile U.S. data sample going back to 1965. Here, in contrast, the shock distributions are based the more-recent sample period of consistent monetary policy going back to 1988. Moreover, Kiley and Roberts (2017) do not allow for the possibility that the natural rate of interest may drift above 1% in their simulations.

In addition to the features noted above, Kiley and Roberts (2017) employ a Taylor rule with no interest rate smoothing. This feature of their model would also appear to contribute to a higher ZLB binding frequency. Table 8 shows the effect of the interest rate smoothing parameter \(\rho\) in the switching model. The baseline case with \(\rho = 0.8\) is compared to the no smoothing case with \(\rho = 0\). For all values of \(\pi^*\), setting \(\rho = 0\) results in a higher ZLB binding frequency, but the episodes exhibit a shorter duration on average. From a ZLB perspective, there appears to be no clear advantage to reducing the degree of interest rate smoothing in the monetary policy rule.

</table>

Note: Model results computed from a 300,000 period simulation.

Following Kiley and Roberts (2017), I use a simple loss function approach to quantify the various trade-offs that are involved in raising the inflation target. The trade-offs here include: (1) reducing the likelihood of endogenous switches to the volatile deflation equilibrium and thereby lowering the ZLB binding frequency, (2) inducing shifts in the volatilities of inflation...
and the output gap, and (3) introducing economic distortions that come from a higher average inflation. The loss function takes the form

\[
Loss = E \left\{ [\pi_{4,t} - 0.02]^2 + \theta [y_t - 0.02 (1 - \beta)/\kappa]^2 \right\},
\]

(22)

where 0.02 and 0.02 (1 - \beta)/\kappa are the long-run endpoints in the targeted equilibrium when \( \pi^* = 0.02 \), as shown in Table 1. The presumption is that the central bank in the baseline calibration with \( \pi^* = 0.02 \) has chosen to target the “optimal” levels of \( \pi_{4,t} \) and \( y_t \). Hence, any shift away from the original target values when adopting \( \pi^* > 0.02 \) would introduce economic distortions that are taken into account by the loss function. Also following Kiley and Roberts (2017), I consider two values for the weight \( \theta \) on the second term that captures the loss from output gap deviations. The bottom rows of Table 7 show that the simple loss function approach would favor a modest increase in the central bank’s inflation target. Specifically, the loss function is minimized at \( \pi^* = 0.03 \) when \( \theta = 1 \) or \( \theta = 0.25 \).

### 4.6 Adaptive learning in a simplified model

Up to this point, I have assumed that the representative agent has full knowledge of the local linear forecast rules associated with each of the two equilibria. While the full-knowledge assumption is standard in models with a unique equilibrium, the computational burden on the agent is higher in the present context. To relax the full-knowledge assumption, I introduce an adaptive learning algorithm in a simplified version of the model. Starting from the original model, the simplified model imposes \( \rho = 0 \), \( \omega = 1 \), \( \rho_v = \rho_u = 0 \), and \( \sigma_\eta = 0 \). These settings eliminate \( i_{t-1}^* \) and \( \pi_{t-1}^* \) as state variables, eliminate the persistence in the shocks \( \nu_t \) and \( u_t \), and cause the natural rate of interest \( r^* \) to be constant. I set \( r^* = 0.0086 \), corresponding to the constant value employed by Aruoba, Cuba-Borda, and Schorfheide (2018). Other parameter values are identical to those in the original model. The theoretical decision rules for each of the two local rational expectations equilibria are shown in Appendix D.

The learning agent employs decision rules that are estimated in real-time using model-generated data. The resulting dynamics are self-referential because the agent’s current decision rules influence the data generated by the model and thereby influence the estimated decision rules in subsequent periods. An equilibrium is said to be “learnable” if the estimated decision rules converge to the theoretical decision rules implied by the rational expectations solution.\(^{25}\)

\(^{25}\)Christiano, Eichenbaum, and Johanssen (2016) consider a more specialized learning experiment in which the ZLB is already binding due to a fundamental shock. Given this condition, they investigate whether various learning algorithms converge to either a high inflation or a low inflation equilibrium.
I consider two versions of the learning algorithm. In the first version, the agent estimates a set of correctly specified decision rules that take the form:

\[ y_t = c_{0,t} + c_{1,t} (r_t - r^*) + c_{2,t} \nu_t + c_{3,t} u_t, \]  

(23)

\[ \pi_t = d_{0,t} + d_{1,t} (r_t - r^*) + d_{2,t} \nu_t + d_{3,t} u_t, \]  

(24)

where the coefficients \( c_{i,t} \) and \( d_{i,t} \) for \( i = 0, 1, 2, 3 \) are estimated each period using an ordinary least squares regression applied to a rolling window of the most recent 32 quarters (8 years) of model-generated data. For the first 32 quarters of the simulation, the coefficient values are set halfway between the two values implied by each of the two local equilibria. I assume that the agent can observe \( r_t, \nu_t, \) and \( u_t \) and knows the laws of motion for all state variables.

In the second version, I assume that the agent estimates a set of misspecified decision rules that omit the terms involving the two white noise shocks \( \nu_t \) and \( u_t \). In both versions, the agent uses the previous period’s estimated decision rules to construct the subjective forecasts

\[ \hat{E}_t y_{t+1} = c_{0,t-1} + c_{1,t-1} \rho_r (r_t - r^*) \]  

and

\[ \hat{E}_t \pi_{t+1} = d_{0,t-1} + d_{1,t-1} \rho_r (r_t - r^*), \]

where the values of \( \rho_r \) and \( r^* \) are assumed known. Use of the previous period’s decision rules to construct the subjective forecasts avoids simultaneity in the realized and forecasted values of the output gap and inflation.

The learning agent’s subjective forecasts are substituted into the global equilibrium conditions (1) and (2). I allow for an occasionally binding ZLB by making the substitution

\[ i_t = 0.5 \bar{i}_t + 0.5 \sqrt{(\bar{i}_t^*)^2} \]  

in the equilibrium condition (1). When combined with a simplified policy rule that imposes \( \rho = 0 \) and \( \omega = 1 \), this procedure yields a system of three equations that can be solved each period to obtain the three realizations \( y_t, \pi_t, \) and \( i_t^* \) given these realizations, the decision rule coefficients are then updated.\(^{26}\)

Figure 11 plots the estimated coefficients \( c_{0,t}, c_{1,t}, d_{0,t}, \) and \( d_{1,t} \) from simulations of the learning algorithm. When the agent estimates correctly specified decision rules (black lines), the coefficients quickly converge to the vicinity of the targeted equilibrium values and remain there. This result shows that the targeted equilibrium is learnable. In contrast, when the agent estimates misspecified decision rules (blue lines), the coefficients exhibit low frequency oscillations that occasionally approach, reach, or go beyond the deflation equilibrium values.

The agent’s failure to control for the shocks \( \nu_t \) and \( u_t \) in the regressions causes the estimated

\(^{26}\)To ensure stability of the learning algorithm, I impose the following projection facility: If the estimated values of \( c_{0,t} \) or \( d_{0,t} \) fall outside the range of two times the targeted equilibrium value on the upside or two times the deflation equilibrium value on the downside, then the agent does not update the affected decision rule for that period only. Intuitively, the agent is assumed to apply a common sense economic restriction on the magnitude of the intercept coefficients in the estimated decision rules.
values of the other coefficients to fluctuate, preventing the algorithm from converging to either of the two equilibria. The low frequency oscillations in the decision rule coefficients induce movements in the macroeconomic variables that are qualitatively similar to those observed in the switching model with full-knowledge. Hence, the basic nature of the switching model dynamics can be preserved in a setting that departs from the full-knowledge assumption.\textsuperscript{27}

It seems reasonable to think that agents might fail to control for some relevant but difficult-to-observe state variables when constructing their conditional forecasts. Along these lines, a recent paper by Busetti, et al. (2017) shows that learning agents’ use of simple autoregressive forecast rules (that omit some relevant state variables) can lead to persistent undershooting of inflation from the central bank’s inflation target. Similarly, Bullard and Cho (2005, p.1842) demonstrate that “certain types of seemingly minor misspecifications along with agent learning might combine to change the global dynamics of the economy in unexpected ways.”

5 Conclusion

Standard New Keynesian models subject to a ZLB exhibit two long-run endpoints (steady states) associated with two local equilibria. Most studies employing New Keynesian models focus on the targeted equilibrium and ignore the possibility of switching to the deflation equilibrium. But there appears to be no clear theoretical or empirical reason why the deflation equilibrium should be ruled out. Indeed, Bullard (2010) concludes that by “promising to remain at zero for a long time,” central banks may inadvertently coordinate private-sector expectations to become stuck in the deflation equilibrium.

I examine a version of the New Keynesian model with a time-varying natural rate of interest and endogenous forecast rule switching based on past performance. The model can produce severe recessions when the exogenous real interest rate gap is persistently negative, causing the representative agent to place a significant weight on the forecast rules associated with the deflation equilibrium. Escape from the deflation equilibrium occurs endogenously when the real interest rate gap eventually starts rising. But even in normal times, a non-trivial weight on the deflation forecast rules may cause the central bank to undershoot its inflation target and magnify the volatilities of macro variables relative to the targeted equilibrium.

I show that the switching model can exactly replicate the observed time paths of the U.S. output gap, quarterly PCE inflation, and the federal funds rate since 1988. The data\textsuperscript{27} Arifovic, Schmitt-Grohé, and Uribe (2018) demonstrate that the deflation equilibrium can be stable under a form of social learning that is governed by a genetic algorithm. A key feature for their result is the initial history of the economy which determines the relative performance among a set of heterogenous forecast rules.
replication exercise tells us that the U.S. data since 2008.Q4 (the start of the ZLB episode) are best described as a mixture of the targeted equilibrium and the deflation equilibrium. This result contrasts with that of Aruoba, Cuba-Borda, and Schorfheide (2018) who do not consider the possibility of a mixed regime but rather examine the likelihood that the recent U.S. economy is best described as being in either a targeted-inflation regime or a deflation regime.

A simple loss function approach favors a modest increase in the central bank’s inflation target to around 3%. But even with an inflation target of 4%, the ZLB binding frequency remains relatively high at 9.5% and the average duration of a ZLB episode is 11.7 quarters. When the deflation equilibrium is taken into account, raising the inflation target is a less effective solution for avoiding long-lived ZLB episodes.
A Appendix: Kalman filter estimate of r-star

Straightforward computations using the laws of motion (5) and (6) yield the following unconditional moments for the first difference of the exogenous real interest rate:

\[ \text{Var}(\Delta r_t) = \sigma^2 \left( \frac{(1 - \rho_r) \phi + 2}{1 + \rho_r} \right), \]  
(A.1)

\[ \text{Var}(\Delta^2 r_t) = \sigma^2 \left( \frac{2(1 - \rho_r)^2 \phi + 6}{1 + \rho_r} \right), \]  
(A.2)

\[ \text{Corr}(\Delta r_t, \Delta r_{t-1-k}) = \frac{(\rho_r \phi - 1) k}{\phi + 2/ (1 - \rho_r)}, \]  
(A.3)

where \( \Delta r_t \equiv r_t - r_{t-1}, \Delta^2 r_t \equiv \Delta r_t - \Delta r_{t-1}, \) and \( \phi \equiv \sigma^2 / \sigma^2 \varepsilon \). Equation (A.3) shows that the values of \( \rho_r \) and \( \phi \) can be inferred from the autocorrelation structure of \( \Delta r_t \), which is observable. Given \( \rho_r \) and \( \phi \), the value of \( \sigma^2 \varepsilon \) can be inferred from (A.1) using the observable value of \( \text{Var}(\Delta r_t) \). Given \( \rho_r \) and \( \sigma^2 \varepsilon \), we have \( \sigma^2 \eta = \sigma^2 \varepsilon \sqrt{\phi} \).

Solving equation (5) for \( r_t^* \) yields:

\[ r_t^* = \frac{r_t - \rho_r r_{t-1}}{1 - \rho_r} - \frac{\varepsilon_t}{\text{Noise}}, \]  
(A.4)

where the first term represents the signal and the second term represents the noise. Equation (6) shows that the Kalman filter estimate of \( r_t^* \), denoted by \( E_t r_t^* \), is a weighted average of the signal and the previous period’s estimate \( E_{t-1} r_{t-1}^* \), where the weight assigned to the signal is the Kalman gain parameter \( \lambda \).

The one step ahead forecast error for \( r_{t+1} \) is given by

\[ \text{err}_{t+1} = r_{t+1} - E_t r_{t+1}, \]

\[ = r_{t+1} - [\rho_r r_t + (1 - \rho_r) E_t r_t^*], \]

\[ = \varepsilon_{t+1} + (1 - \rho_r) \eta_{t+1} + (1 - \rho_r) (r_t^* - E_t r_t^*), \]  
(A.5)

where the last term in (A.5) represents the estimation error for \( r_t^* \). The optimal value of \( \lambda \) minimizes the mean squared forecast error, as given by

\[ E(\text{err}_{t+1}^2) = \sigma^2 \varepsilon \left[ 1 + (1 - \rho_r)^2 \phi \right] + (1 - \rho_r)^2 \text{Var}(r_t^* - E_t r_t^*). \]  
(A.6)

where \( \text{Var}(r_t^* - E_t r_t^*) \) is the unconditional variance of the estimation error.

The law of motion for the estimation error follows directly from equation (9) and can be written as

\[ r_t^* - E_t r_t^* = \lambda \left[ \frac{\varepsilon_t - \rho_r \varepsilon_{t-1}}{1 - \rho_r} \right] + (1 - \lambda) (r_{t-1}^* - E_{t-1} r_{t-1}^*) - \left[ \frac{1 - \lambda - \rho_r}{1 - \rho_r} \right] \eta_t, \]  
(A.7)
where \( z_t \equiv r_t - r_t^* \) is the actual real rate gap. The law of motion for \( z_t \) follows directly from equations (5) and (6) and can be written as

\[
z_t = \rho_r z_{t-1} - \rho_r \eta_t + \varepsilon_t. \tag{A.8}
\]

Starting from equations (A.7) and (A.8), we can compute the following expression for the unconditional variance of the estimation error

\[
Var (r_t^* - E_t r_t^*) = \sigma_\varepsilon^2 \left\{ \frac{\lambda (\rho_r^2 \phi + 1) + (1 - \lambda - \rho_r) [(1 - \lambda) (1 - \rho_r) / \lambda + \rho_r] \phi}{(2 - \lambda) (1 - \rho_r)^2} \right\}, \tag{A.9}
\]

which can be substituted into equation (A.6) to obtain a complicated expression for \( E (err_t^2) \) in terms of \( \lambda \). From this expression, we can compute the gradient

\[
\frac{\partial E (err_t^2)}{\partial \lambda} = \frac{2 \left[ \lambda^2 - (1 - \lambda) (1 - \rho_r)^2 \phi \right]}{(2 - \lambda)^2 \lambda^2}. \tag{A.10}
\]

Setting the gradient equal to zero yields a quadratic equation in \( \lambda \). The root that minimizes \( E (err_t^2) \) is given by equation (10).

**B Appendix: Targeted equilibrium**

To solve for the local linear forecast rules associated with the targeted equilibrium, I assume that \( i_t^* = i_t > 0 \) for all \( t \). This assumption is valid in a vicinity of the targeted equilibrium’s long-run endpoints. Starting from equation (11) we have:

\[
i_t^* = \rho i_{t-1}^* + (1 - \rho) \left[ E_t r_t^* + \pi^* + g_\pi (\pi_t - \pi^*) + g_\pi (1 - \omega) (\pi_{t-1} - \pi^*) + g_y (y_t - y^*) \right] \tag{B.1}
\]

where I have used equation (12) to eliminate \( \pi_t \).

Equation (B.1) together with the Euler equation (1) and the Phillips curve (2) form a linear system of three equations in the three unknown decision rules for \( y_t, \pi_t, \) and \( i_t^* \). The state variables are: \( r_t, E_t r_t^*, \pi_{t-1}, i_{t-1}^*, \nu_t, \) and \( u_t \). Standard techniques yield a set of linear decision rules of the form

\[
\begin{bmatrix}
y_t - \pi^* (1 - \beta) / \kappa \\
\pi_t - \pi^* \\
i_t^* - (E_t r_t^* + \pi^*)
\end{bmatrix} = A \begin{bmatrix}
r_t - E_t r_t^* \\
\pi_{t-1} - \pi^* \\
i_{t-1}^* - E_t r_t^* - \pi^* \\
\nu_t \\
u_t
\end{bmatrix}, \tag{B.2}
\]

32
where $A$ is a $3 \times 5$ matrix of decision rule coefficients. For the parameter values shown in Table 2, the matrix $A$ is

$$
A = \begin{bmatrix}
0.594 & -0.153 & -0.386 & 3.221 & -0.174 \\
0.069 & -0.017 & -0.033 & 0.275 & 1.396 \\
0.128 & 0.129 & 0.718 & 0.682 & 0.158
\end{bmatrix}.
$$

(B.3)

Iterating the linear decision rules in (B.2) ahead one period and then taking the conditional expectation of both sides yields the following set of linear forecast rules associated with the targeted equilibrium:

$$
E_t y_{t+1} = y^* + A_{11} \rho_t (r_t - E_t r_t^*) + A_{12} (\pi_t - \pi^*) + A_{13} (i_t^* - E_t r_t^* - \pi^*) + A_{14} \rho_t \nu_t + A_{15} \rho_t u_t,
$$

(B.4)

$$
E_t \pi_{t+1} = \pi^* + A_{21} \rho_t (r_t - E_t r_t^*) + A_{22} (\pi_t - \pi^*) + A_{23} (i_t^* - E_t r_t^* - \pi^*) + A_{24} \rho_t \nu_t + A_{25} \rho_t u_t,
$$

(B.5)

where $A_{i,j}$ represents the corresponding element of the matrix $A$ and I have substituted in $E_t (r_{t+1} - E_{t+1} r_{t+1}^*) = \rho_r (r_t - E_t r_t^*)$. Notice that the forecast rules depend on the realization of $\pi_t$ because $\pi_t$ depends on $\pi_t$ via equation (12). Also, the forecast rules depend on the realization of $i_t^*$ due to the interest rate smoothing term in (B.1). Hence, the model allows for simultaneity between the forecasted and realized values of $\pi_t$ and $i_t^*$. Neither the agent nor the central bank are required to forecast $i_t^*$.

The local linear forecast rules (B.4) and (B.5) are derived under the assumption that the ZLB is never binding. However, in the stochastic simulation of the targeted equilibrium, I allow for an occasionally binding ZLB. When simulating the model, I substitute the local linear forecast rules given by (B.4) and (B.5) into the global equilibrium conditions (1) and (2). I allow for an occasionally binding ZLB by making the substitution $i_t = 0.5 i_t^* + 0.5 \sqrt{(i_t^*)^2}$ in the equilibrium condition (1). Together with the monetary policy rule (B.1), this procedure yields a system of three equations that are solved each period to obtain the three realizations $y_t$, $\pi_t$, and $i_t^*$.

C Appendix: Deflation equilibrium

To solve for the local linear forecast rules associated with the deflation equilibrium, I assume $i_t^* \leq 0$ such that $i_t = 0$ for all $t$. This assumption is valid in a vicinity of the deflation equilibrium’s long-run endpoints. Equation (B.1) applies unchanged to the deflation equilibrium,
as does the Phillips curve (2). However, due to the binding ZLB, the Euler equation (1) now becomes

\[ y_t = E_t y_{t+1} + \alpha[E_t \pi_{t+1} + r_t] + \nu_t. \]  

Equation (C.1) together with equations (B.1) and (2) form a linear system of three equations in the three unknown decision rules for \(y_t, \pi_t,\) and \(i_t^\ast\). The state variables are: \(r_t, E_t r_t^\ast, \pi_{t-1}, i_{t-1}^\ast, \nu_t,\) and \(u_t\). The minimum state variable (MSV) solution yields a set of linear decision rules of the form

\[
\begin{bmatrix}
  y_t - (-E_t r_t^\ast) (1 - \beta) / \kappa \\
  \pi_t - (-E_t r_t^\ast) \\
  i_t^\ast - (E_t r_t^\ast + \pi^*) [1 - g_\pi - g_y (1 - \beta) / \kappa]
\end{bmatrix} = \mathbf{B} \begin{bmatrix}
  r_t - E_t r_t^\ast \\
  \pi_{t-1} - (-E_t r_t^\ast) \\
  i_{t-1}^\ast - (E_t r_t^\ast + \pi^*) [1 - g_\pi - g_y (1 - \beta) / \kappa] \\
  \nu_t \\
  u_t
\end{bmatrix},
\]

where \(\mathbf{B}\) is a \(3 \times 5\) matrix of constant coefficients. The MSV solution implies \(B_{12} = B_{22} = 0\) and \(B_{13} = B_{23} = 0\). For the parameter values shown in Table 2, the matrix \(\mathbf{B}\) is

\[
\mathbf{B} = \begin{bmatrix}
  1.247 & 0 & 0 & 5.397 & 0.092 \\
  0.213 & 0 & 0 & 0.661 & 1.429 \\
  0.279 & 0.162 & 0.8 & 1.171 & 0.215
\end{bmatrix}.
\]

Comparing the first column of matrix \(\mathbf{B}\) in (C.3) to the first column of matrix \(\mathbf{A}\) in (B.3) shows that a shock to \(r_t - E_t r_t^\ast\) will be transmitted more forcefully to macro variables in the deflation equilibrium than in targeted equilibrium. Specifically, we have

\[
\frac{B_{11}}{A_{11}} = 2.1, \quad \frac{B_{21}}{A_{21}} = 3.1, \quad \frac{B_{31}}{A_{31}} = 2.2.
\]

For the special case when \(\rho = 0\) and \(\omega = 1\), it is straightforward to derive the following analytical relationship between the decision rule coefficients for the two local equilibria:

\[
\frac{B_{11}}{A_{11}} = \frac{B_{21}}{A_{21}} = \frac{B_{31}}{A_{31}} = 1 + \frac{\alpha [g_\pi (1 - \beta \rho_r) g_y]}{(1 - \beta \rho_r) (1 - \rho_r) - \alpha \kappa \rho_r} > 1.
\]

Iterating the linear decision rules in (C.2) ahead one period and then taking the conditional expectation of both sides yields the following set of local linear forecast rules for the deflation equilibrium:

\[
E_t y_{t+1} = -E_t r_t^\ast (1 - \beta) / \kappa + B_{11} \rho_r (r_t - E_t r_t^\ast) + B_{14} \rho_r \nu_t + B_{15} \rho_u u_t, \quad \text{(C.6)}
\]
\[
E_t \pi_{t+1} = -E_t r_t^\ast + B_{21} \rho_r (r_t - E_t r_t^\ast) + B_{24} \rho_r \nu_t + B_{25} \rho_u u_t, \quad \text{(C.7)}
\]
where the MSV solution implies $B_{12} = B_{22} = 0$ and $B_{13} = B_{23} = 0$ and I have substituted in

$$E_t \left( r_{t+1} - E_{t+1} r^*_t \right) = \rho_r (r_t - E_t r^*_t).$$

Neither the agent or the central bank are required to forecast $i^*_{t+1}$.

The local linear forecast rules (C.6) and (C.7) are derived under the assumption that the ZLB is always binding. However, in the stochastic simulation of the deflation equilibrium, I allow for an occasionally binding ZLB. When simulating the model, I substitute the local linear forecast rules given by (C.6) and (C.7) into the global equilibrium conditions (1) and (2). I allow for an occasionally binding ZLB by making the substitution $i_t = 0.5 i^*_t + 0.5 \sqrt{(i^*_t)^2}$ in the equilibrium condition (1). Together with the monetary policy rule (B.1), this procedure yields a system of three equations that are solved each period to obtain the three realizations $y_t$, $\pi_t$, and $i^*_t$.

D Appendix: Simplified model for adaptive learning

This appendix provides the theoretical equilibrium decision rules for the simplified model that is used in the adaptive learning algorithm described in Section 4.6. Starting from the original model, the simplified model imposes $\rho = 0$, $\omega = 1$, $\rho_\nu = \rho_u = 0$, and $\sigma_\eta = 0$. These settings eliminate $i^*_{t-1}$ and $\pi_{t-1}$ as state variables, eliminate the persistence in the shocks $\nu_t$ and $u_t$, and cause the natural rate of interest $r^*$ to be constant.

The targeted equilibrium decision rules are

$$\begin{bmatrix} y_t - \pi^*(1 - \beta) / \kappa \\ \pi_t - \pi^* \\ i^*_t - (r^* + \pi^*) \end{bmatrix} = A \begin{bmatrix} r_t - r^* \\ \nu_t \\ u_t \end{bmatrix}, \quad (D.1)$$

where the elements of the matrix $A$ are given by

$$A = \begin{bmatrix} \alpha (1 - \beta \rho_r) (1 - \rho_r + \alpha g_y) (1 - \beta \rho_r) + \alpha \kappa (g_\pi - \rho_r) & 1 & 1 \\ \alpha \kappa & 1 + \alpha \kappa g_\pi + \alpha g_y & 1 + \alpha \kappa g_\pi + \alpha g_y \\ \alpha \kappa g_\pi + g_y (1 - \beta \rho_r) & \kappa & 1 + \alpha g_y \\
(1 - \rho_r + \alpha g_y) (1 - \beta \rho_r) + \alpha \kappa (g_\pi - \rho_r) & 1 + \alpha \kappa g_\pi + \alpha g_y & 1 + \alpha \kappa g_\pi + \alpha g_y \\ \alpha \kappa g_\pi + g_y (1 - \beta \rho_r) & \kappa & 1 + \alpha g_y \\
(1 - \rho_r + \alpha g_y) (1 - \beta \rho_r) + \alpha \kappa (g_\pi - \rho_r) & 1 + \alpha \kappa g_\pi + \alpha g_y & 1 + \alpha \kappa g_\pi + \alpha g_y \end{bmatrix}. \quad (D.2)$$

The deflation equilibrium decision rules are

$$\begin{bmatrix} y_t - (-r^*) (1 - \beta) / \kappa \\ \pi_t - (-r^*) \end{bmatrix} = B \begin{bmatrix} r_t - r^* \\ \nu_t \\ u_t \end{bmatrix}, \quad (D.3)$$

The targeted equilibrium decision rules are

$$\begin{bmatrix} y_t - (-r^*) (1 - \beta) / \kappa \\ \pi_t - (-r^*) \end{bmatrix} = B \begin{bmatrix} r_t - r^* \\ \nu_t \\ u_t \end{bmatrix}, \quad (D.3)$$
where the elements of the matrix $B$ for the MSV solution are given by

$$
B = \begin{pmatrix}
\frac{\alpha (1 - \beta \rho_r)}{(1 - \rho_r) (1 - \beta \rho_r) - \alpha \kappa \rho_r} & 1 & 0 \\
\frac{\alpha \kappa}{(1 - \rho_r) (1 - \beta \rho_r) - \alpha \kappa \rho_r} & \kappa & 1 \\
\frac{\alpha (1 - \beta \rho_r)}{(1 - \rho_r) (1 - \beta \rho_r) - \alpha \kappa \rho_r} & \kappa \pi + g_y & g_\pi
\end{pmatrix}.
$$

Williamson., S. 2017a Low Real Interest Rates and Monetary Policy, New Monetarist Economics (March 29).

Nominal interest rates in the United States encountered the zero lower bound during the 1930s and from 2008.Q4 though 2015.Q4. Nominal interest rates in Japan have remained near zero since 1998.Q3, except for the relatively brief period from 2006.Q4 to 2008.Q3. Nominal interest rates in Switzerland have been zero or slightly negative since 2008.Q4. Nominal interest rates in the United Kingdom have been approximately zero since 2009.Q1. Outside of these episodes, all four countries exhibit a strong positive correlation between nominal interest rates and inflation, consistent with the Fisher relationship.
The two intersections of the ZLB-augmented monetary policy rule (solid red line) with the Fisher relationship (dashed black line) define two long-run endpoints, labeled the “targeted equilibrium” and “deflation equilibrium,” respectively. The monetary policy rule is $i_t = r^* + \pi^* + g_\pi (\pi_{4,t} - \pi^*)$ with $r^* = 0.01, \pi^* = 0.02$ and $g_\pi = 1.5$. The Fisher relationship is $i_t = r^* + \pi_{4,t}$. 

Figure 2: U.S. Nominal Interest Rates and Inflation
The real federal funds rate (blue line) is defined as the nominal federal funds rate minus expected quarterly inflation computed from a rolling 40-quarter, 4-lag vector autoregression that includes the nominal funds rate, quarterly PCE inflation (annualized), and the CBO output gap. The correlation coefficient between the real federal funds rate and the “efficient real rate” constructed by Curdia et al. (2015) is 0.83. The time series process for the Kalman filter estimate of the natural rate of interest in the model (dotted green line) is calibrated to approximate the one-sided estimate of the U.S. natural rate series (dashed red line) from Laubach and Williams (2016, updated) for the period of consistent monetary policy from 1988.Q1 to 2017.Q2.
The real federal funds rate has remained mostly below the Laubach-Williams estimate of \( r_t \) since early 2009. The nominal federal funds rate was approximately zero from 2008.Q4 through 2015.Q4. A Taylor-type rule of the form (11) using the parameter values in Table 2, with \( E_t r_t^* \) given by Laubach-Williams estimate, \( \pi_t \) given by the 4-quarter PCE inflation rate, and \( y_t \) given by the CBO output gap predicts that the desired nominal funds rate was negative starting in 2009.Q1 and remains negative through 2016.Q4. The 4-quarter PCE inflation rate was briefly negative in 2009 and has remained below the Fed’s 2% inflation target since 2012.Q2. The Great Recession was very severe, pushing the CBO output gap down to \(-6.3\%\) at the business cycle trough in 2009.Q2. The output gap remains negative at \(-0.2\%\) in 2017.Q2, eight years after the Great Recession ended. The various endpoints plotted in the figure are computed using the expressions in Table 1, with \( r_t^* \) given by the Laubach-Williams estimate. As \( r_t^* \) approaches zero or becomes negative, the “deflation” equilibrium is characterized by zero or low inflation, allowing this equilibrium to provide a better fit of recent U.S. inflation data.
Figure 5: Measures of Expected U.S. Inflation

Market-based measures of expected inflation from zero coupon inflation swap contracts and Treasury Inflation Protected Securities (TIPS) dropped sharply in 2008.Q4, coinciding with the start of the ZLB episode. The market-based measures remain below the Fed’s 2% inflation target at the end of the data sample. The median 1-year expected inflation rate from the Survey of Professional Forecasters (SPF) dropped sharply in 2008.Q4 and has recovered slowly to a level that is below its pre-recession range. The 10-year survey measure does not exhibit a sharp drop in 2008.Q4, but has since trended downward to a level that is below its pre-recession range. The Federal Reserve Bank of St. Louis’ Price Pressures Measure (PPM) represents the probability that the 4-quarter PCE inflation rate over the next year will exceed 2.5%. The PPM dropped sharply in 2008.Q4 and is currently hovering around a probability of 10%.
Given the U.S. data counterparts for the model variables, we can solve for the implied time series of stochastic shocks and endogenous forecast rule weights that allow the switching model to exactly replicate the observed U.S. time paths of the CBO output gap, PCE inflation, and the federal funds rate since 1988. The reverse-engineered shocks $\nu_t$ and $u_t$ become strongly negative at the start of the ZLB episode in 2008.Q4. The top right panel shows that the performance gap between the two sets of local linear forecast rules starts to narrow considerably after 2008.Q4, causing the weight $\mu_t$ on the targeted forecast rules to decline. The bottom right panel shows that the weight drops sharply during the Great Recession, but then declines more gradually afterwards. At the end of the data sample, the value of $\mu_t$ is 0.56, helping the switching model to account for the persistent undershooting of the Fed’s 2% inflation target since mid-2012. The bottom left panel compares the 1-year expected inflation rate from U.S. inflation swaps to the path of $\tilde{E}_t \pi_{t+1}$ from the switching model. The correlation coefficient between the two series is 0.81. Both series remain below 2% at the end of the data sample in 2017.Q2.
When the exogenous real interest gap $r_t - E_t r^*_t$ is negative for a sustained period (top panel), the resulting downward pressure on $y_t$ and $\pi_t$ serves to reduce the recent $RMSFE$ of the deflation forecast rules and increase the recent $RMSFE$ of the targeted forecast rules (middle panel). Around period 1725, the shift in relative forecast performance induces the agent to reduce the weight on the targeted forecast rules. The lower weight puts further downward pressure on $y_t$ and $\pi_t$, causing the deflation equilibrium to eventually become fully realized around period 1750 (bottom panel). Around period 1800, the real rate gap once again becomes positive, causing the $RMSFE$ of the deflation forecast rules to exceed the $RMSFE$ of the targeted forecast rules. The agent increases the weight on the targeted forecast rules, causing the targeted equilibrium to be restored. Qualitatively similar results are obtained if the agent employs a logistic rule along the lines of Binning and Maih (2017) to compute the weight on the targeted forecast rules.
Model variables in the deflation equilibrium have distributions with lower means but higher variances than those in the targeted equilibrium. But the significant overlap in the various distributions creates a dilemma for an agent who seeks to determine the likelihood that a string of recent data observations are drawn from one equilibrium or the other. Variables in the switching model have means that are somewhat lower and variances that are somewhat higher than those in the targeted equilibrium. Consequently, the central bank in the switching model undershoots its inflation target and the volatilities of the output gap and inflation are both higher relative to the targeted equilibrium.
Unlike the targeted equilibrium, the switching model can produce infrequent but long-lived ZLB episodes in response to small, normally distributed shocks. A 29 quarter ZLB episode (the duration observed in U.S. data) is an extremely rare event in the targeted equilibrium but can occur with about 5% frequency in the switching model. To account for infrequent but long-lived ZLB episodes, the targeted equilibrium would require large shocks that are themselves infrequent and long-lived, as in Dordal-i-Carreras, et al. (2016).
All three model versions employ the same sequence of stochastic shocks. Around period 1725, the weight on the targeted forecast rules in the switching model starts dropping toward zero, causing the deflation equilibrium to become fully realized. The episode results in a negative desired nominal policy rate, a binding ZLB, a highly negative output gap, and brief deflation followed by below-target inflation, reminiscent of the Great Recession and its aftermath.
Starting from the original model, the simplified model imposes $\rho = 0$, $\omega = 1$, $\rho_u = \rho_\pi = 0$, and $\sigma_\pi = 0$. These settings eliminate $i_{t-1}$ and $\pi_{t-1}$ as state variables, eliminate the persistence in the shocks $\nu_t$ and $u_t$, and cause the natural rate of interest $r^*$ to be constant. When the agent estimates correctly specified decision rules (black lines), the coefficients quickly converge to the vicinity of the targeted equilibrium values and remain there. In contrast, when the agent estimates misspecified decision rules that fail to control for the white noise shocks $\nu_t$ and $u_t$ (blue lines), the coefficients exhibit low frequency oscillations that can occasionally approach, reach, or go beyond the deflation equilibrium values. The low frequency oscillations in the decision rule coefficients induce movements in the macroeconomic variables that are qualitatively similar to those observed in Figure 10 for the switching model with full-knowledge.
