

# Variance Risk Premia in Commodity Markets\*

Marcel Prokopczuk<sup>†,‡</sup> and Chardin Wese Simen<sup>§</sup>

November 9, 2014

## Abstract

We use a large panel of commodity option prices to study the market price of variance risk. We construct synthetic variance swaps and find significantly negative variance risk premia in nearly all commodity markets. An equally-weighted portfolio of short commodity variance swaps earns an annualized Sharpe Ratio of around 40%. We document increasing comovements across bonds, commodities and equity variance swap returns, suggesting that the variance swap markets are increasingly integrated. Finally, we show that commodity variance risk premia are distinct from price risk premia, indicating that variance risk is unspanned by commodity futures.

**JEL classification:** G12, G13

**Keywords:** Commodities, Variance risk premia, Variance swaps

# 1 Introduction

Over the past decade, commodity markets have witnessed tremendous increases in volatility. Given their role as consumption goods, factors of production and financial assets, managing commodity volatility is crucial for a wide number of market participants such as commercial hedgers and investors. Arguably, these developments have motivated the successful launch of commodity related volatility derivatives such as oil and gold VIX futures contracts. The rapid proliferation of these derivatives raises several questions. Chief among them include: how large is the compensation required by investors to bear variance risk in commodity markets? Are there commonalities in commodity variance risk premia? How do commodity variance risk premia relate to bond and equity variance risk premia? What effect, if any, does the financialization of commodity markets have on the market price of variance risk? What is the relationship between price and variance risk premia? These are some of the questions we seek to answer.

In this paper, we comprehensively analyze the market price of variance risk in 21 commodity markets between 1989 and 2011, a period which includes the recent financial crisis. In doing so, we make three important contributions to the literature. First, we use a large panel of futures and options data to construct synthetic commodity variance swaps. This is important as commodity variance swaps allow us to estimate the market price of variance risk in a model-free way. Variance swaps are made up of a fixed leg, the variance swap rate, and a floating leg, the realized variance. Each day, we combine static positions in option contracts to replicate the variance swap rate. We obtain the floating leg by computing the realized variance of the underlying commodity over the maturity of the variance swap.

We then estimate commodity variance risk premia as the sample average of the difference between the floating and fixed legs of variance swaps (Carr and Wu, 2009; Driessen et al., 2009). Analyzing variance swaps that mature in 60 and 90 days, we find significant variance risk premia in virtually all commodity markets.<sup>1</sup> This is in contrast to the results of Carr and Wu (2009) and Driessen et al. (2009), who find very limited evidence of variance risk premia in individual equities.<sup>2</sup> Typically, commodity variance risk premia are negative and economically large. Our analysis reveals that investments in commodity variance swaps offer attractive rewards. An equally-weighted portfolio of short commodity variance swaps yields an annualized Sharpe Ratio of 40 %.

Our second novel contribution consists in providing the first analysis of commonalities in variance swap returns. Our investigation proceeds in three steps. First, we focus on comovements within commodity sectors. To achieve this goal, we group commodities into sectors, i.e. energy, grains, livestock, metals, tropical, and wood. For each sector, we compute the average pair-wise correlation of commodity variance swap returns. We find modest correlations between variance swap returns of similar commodities. For example, the average pair-wise correlation among energy commodity variance swap returns is around 33 %. Second, we investigate commonalities across sectors. For each commodity sector, we compute an equally-weighted portfolio of variance swap returns. We then study the comovement across distinct sectors and find unconditional correlation coefficients that are generally below 20 %. Third, we analyze how commodity, Treasury and S&P 500 variance swap returns interact with each other. Our analysis reveals modest (typically below 30 %) unconditional correla-

---

<sup>1</sup>Typically, commodity options have bimonthly or quarterly expiration cycles. As a result, we focus on variance swaps that mature in 60 and 90 days.

<sup>2</sup>Carr and Wu (2009) report significantly negative variance risk premia in 8 out of 35 individual equities only. Similarly, Driessen et al. (2009) find significant variance risk premia in 29 out of 127 individual stocks.

tions across asset classes. Motivated by the literature on the financialization of commodity markets (Tang and Xiong, 2012), we partition our sample into two distinct subperiods. The first subperiod, which we label “pre-financialization”, ends in November 2004. The “financialization” period, which captures the period of increased investor flows in commodity markets, runs from December 2004 onward. We confirm that variance risk is significantly priced during each of these subperiods. More importantly, we uncover increasing comovements in variance swap returns. The case of energy markets is particularly telling. Prior to December 2004, equity and energy variance swap returns are only weakly correlated, as evidenced by their low correlation coefficient (2.62%). However, this correlation rises to around 48% during the period of financialization. This finding indicates that the financialization of commodity markets is a pervasive phenomenon that affects not only the risk premia related to the first but also the second moment of commodity returns.

Our third contribution consists in investigating the relationship between commodity *variance* risk premia on the one hand and equity, bond and commodity *price* risk premia on the other. This analysis sheds light on the extent to which variance risk premia may be explained by traditional risk factors. To do so, we follow a three-pronged approach. First, we examine the relationship between commodity variance risk premia and the determinants of equity returns. This is interesting because our findings of negative variance risk premia may be explained by a significantly negative correlation between innovations to the variance of a commodity and equity risk factors. To investigate this possibility, we regress commodity variance risk premia on the 3 factors of Fama and French (1993). We find that the coefficient loadings on the risk factors are not statistically distinguishable from zero, indicating that commodity variance risk premia are unrelated to equity risk factors such as the market risk

premium. Second, we analyze the relationship between commodity variance risk premia and bond risk premia. We use the Cochrane and Piazzesi (2005) and Ludvigson and Ng (2009) factors as determinants of bond risk premia and regress commodity variance swap returns on these factors, obtaining very low explanatory power. Typically, the coefficient loadings on the independent variables are statistically insignificant, suggesting that commodity variance risk premia are independent the macroeconomic risk factors that drive bond risk premia. Finally, we analyze the link between the variance risk premium of a commodity and its price risk premium by regressing the former on the latter. Our regression model yields very low explanatory power and mainly insignificant slope estimates. These results indicate that variance risk premia are largely orthogonal to price risk premia. In other words, commodity variance risk is not spanned by commodity futures, suggesting that options contracts are non-redundant securities.

We perform several checks to establish the robustness of our main results. First, we investigate whether expected (rather than realized) commodity variance risk premia are also significantly negative. To this end, we use historical variance as a proxy for expected variance to compute the floating leg of variance swaps and repeat our investigation. We show that expected commodity variance risk premia are significantly negative, strengthening our conclusion that investors are willing to pay a large premium to hedge commodity variance risk. We then analyze the robustness of the methodology underpinning our variance swap rate estimates. To begin with, we use a cubic spline (rather than linear) interpolation technique and obtain similar results. We also use different truncation points and find that they do not materially affect our core findings. Additionally, we assess the effect of jumps on the variance risk premia estimates and demonstrate that they do not change our main

conclusions: there are significantly negative variance risk premia in commodity markets. Moreover, we demonstrate that our synthetic swap rates are highly correlated with publicly available indices. We take several steps to establish that our results are robust to concerns related to the tradability of options on commodity futures. We also analyze the impact of seasonality on our main results. In a first step, we regress variance swap returns on twelve monthly dummies to purge out potential seasonal fluctuations. We then repeat our main analyses and find little differences with our baseline results. Finally, we use non-overlapping samples of variance swaps and obtain similar results, demonstrating that our results are robust to overlapping observation concerns.

Our paper adds to the works of Coval and Shumway (2001), Bakshi and Kapadia (2003a), Bakshi and Kapadia (2003b), Carr and Wu (2009), Driessen et al. (2009), Trolle and Schwartz (2010), Wang et al. (2011) and Mueller et al. (2013), who study the market price of variance risk in a range of markets. Bakshi and Kapadia (2003a) and Bakshi and Kapadia (2003b) use a delta-hedging approach and find significant volatility risk premia in individual equities. Using a different methodology and sample period, Carr and Wu (2009) and Driessen et al. (2009) reach the opposite findings. They construct synthetic variance swaps and find little evidence of variance risk premia in individual equities. The conflicting evidence reported in extant studies may be due to their fairly short sample periods and different methodologies, which make the results difficult to compare and interpret. To our knowledge, we present the most comprehensive study on commodity variance risk premia. We build on the model-free approach of Carr and Wu (2009) to analyze the market price of variance risk over several decades in more than 20 commodity markets. Covering a long time series is crucial in order to draw robust inferences about the dynamics of variance risk premia. Additionally, covering

a large number of markets allows us to present the first study on comovements in commodity variance risk.

Our work also relates to the literature on commodity futures risk premia. Gorton et al. (2013), Daskalaki et al. (2014) and Szymanowska et al. (2014), among others, study commodity futures risk premia. We analyze a different type of risk premium. Indeed, we focus on the compensation that investors require for bearing variance (rather than price) risk in commodity markets. We establish that, contrary to price risk premia, commodity variance risk premia are significantly negative and economically large. Our analysis reveals that the Sharpe Ratio of a strategy that earns the variance risk premium is 4 times larger than that of a strategy that captures the futures risk premium.

We also contribute to the growing literature on the integration of commodity markets with traditional asset classes. Recent works by Tang and Xiong (2012) and Singleton (2014) study the financialization of commodity markets and its effect on the risk premium related to the first moment of commodity returns. They show that commodity returns are increasingly integrated with returns on traditional asset classes. We complement this literature by documenting similar effects for the risk premium associated with the second moment of commodity returns: commodity variance swap returns are increasingly correlated with bond and equity variance swap returns. Thus, we are the first to provide direct and model-free evidence that the financialization of commodity markets is a pervasive phenomenon that affects both the futures and options markets.

Our study carries interesting implications for risk management in commodity markets. The existence of large variance risk premia in commodity markets challenges the common practice of relying on implied variance to obtain unbiased forecast of future variance. To

obtain a more accurate prediction of future variance, the forecaster must specifically account for the role of the variance risk premium. Failure to do so would result in biased forecasts and suboptimal risk management decisions. Our finding that variance swap returns are largely orthogonal to price risk premia also suggests that variance risk cannot be hedged by trading in the corresponding commodity futures market. A direct implication of this result is that variance risk is unspanned by commodity futures, making options contracts non-redundant securities. Evidently, a good model of commodity prices should feature unspanned stochastic volatility.

Finally, our paper presents new empirical facts that must be captured by general equilibrium models. Up to this point, the theoretical literature on variance risk premia focuses exclusively on the dynamics of the variance risk premium embedded in options on the S&P 500 index (Bollerslev et al., 2009; Drechsler and Yaron, 2011). Consequently, variance premia in individual markets are less studied. We present a rich set of facts about commodity variance risk that must be replicated by theoretical models. For example, it would be particularly interesting to develop a model to explain why variance risk is priced in individual commodities, while it is not priced in individual equities. We hope that our results will guide the development of more general models that are able to capture the rich dynamics of variance risk across asset classes.

This paper proceeds as follows. In Section 2 we introduce our methodology and describe the data set employed. In Section 3 we present and discuss our empirical results. Finally, Section 4 concludes.

## 2 Methodology and Data

### 2.1 Methodology

Empirical studies on variance risk premia are usually anchored around one of the following three estimation approaches: parametric, semi-parametric or model-free. The parametric approach consists of specifying a data-generating process for the underlying. In this framework, the variance risk premium is usually a parameter to be estimated by exploiting information from the underlying and options prices. This approach is not only computationally intensive but also subject to specification errors since it explicitly assumes a particular data-generating process for the underlying. Consequently, parametric estimates of variance risk premia are joint tests of model specification and variance risk premia. Broadie et al. (2007) empirically examine the impact of model misspecification on risk premia. They conclude that the significance of variance risk premia depends crucially on assumptions about the presence of jumps in the data-generating process.<sup>3</sup>

Bakshi and Kapadia (2003a) propose to study variance risk premia in a semi-parametric manner by analyzing the profitability of delta-hedged straddles. This approach builds on the insights of financial theory, which posits that option prices are affected by changes in implied volatility and the underlying's price. Since delta-neutral straddles are insensitive to small movements of the underlying's price, their profitability is mainly driven by changes in implied volatility. Hence, the profitability of delta-neutral straddles may shed light on the existence of volatility risk premia. Though intuitive, this approach is still vulnerable to the

---

<sup>3</sup>Pan (2002) reaches similar conclusions. The author shows that once jumps are allowed for, the variance risk premium becomes insignificant in her data set.

criticism that it relies on a specific hedging model.

To overcome these problems, the more recent model-free approach builds on variance swaps defined as swap contracts in which the floating leg corresponds to the realized variance of the underlying over a predetermined period. The underlying idea is that unconditional variance risk premia are equal to the sample averages of variance swap pay-offs, defined as the differences between the realized variance and the risk-neutral expectation of variance. No-arbitrage arguments imply that the variance swap rate,  $SV_{t,T}$ , must be equal to the risk-neutral expectation of variance,  $\mathbb{E}_t^Q(V_{t,T})$ , over the life of the swap. Thus, the unconditional variance risk premium can be estimated as the sample average of variance swap pay-offs. The pay-off ( $VRP_{t,T}$ ) to a variance swap contract (with a notional of 1) for the period ranging from  $t$  to  $T$  is given by:

$$VRP_{t,T} = RV_{t,T} - SV_{t,T} \tag{1}$$

$$\equiv RV_{t,T} - \mathbb{E}_t^Q(V_{t,T}) \tag{2}$$

where  $VRP_{t,T}$  is the annualized variance risk premium between  $t$  and  $T$ .  $RV_{t,T}$  denotes the annualized realized variance between  $t$  and  $T$  under the physical measure.  $SV_{t,T}$  is the annualized variance swap rate, which is equal to the risk-neutral expectation of variance  $\mathbb{E}_t^Q(V_{t,T})$ .

Consequently, quantifying variance risk premia reduces to estimating realized variance and variance swap rates. Whilst realized variance estimators have been extensively studied (see, e.g., Andersen et al. (2009) and the references therein), until recently, little has been known about the latter. Britten-Jones and Neuberger (2000) and Jiang and Tian (2005)

elaborate a static replicating strategy to estimate the variance swap rate under the assumption that the underlying return follows a general jump-diffusion process.<sup>4</sup> More precisely, they derive the following relationship:<sup>5</sup>

$$\mathbb{E}_t^Q(V_{t,T}) = MFIV_{t,T} = 365 \times \frac{2e^{r_t \frac{T-t}{365}}}{T-t} \left[ \int_0^{F_{t,T}} \frac{P(t, K, T)}{K^2} dK + \int_{F_{t,T}}^{+\infty} \frac{C(t, K, T)}{K^2} dK \right] \quad (3)$$

where  $\mathbb{E}_t^Q(V_{t,T})$  and  $MFIV_{t,T}$  refer to the annualized risk-neutral expectation of variance and model-free implied variance between  $t$  and  $T$ , respectively. We assume 365 calendar days in a year. The annualized risk-free rate is denoted by  $r_t$ .  $F_{t,T}$  denotes the futures contract observed at time  $t$  and expiring at  $T$ .  $P(t, K, T)$  and  $C(t, K, T)$  denote the price at time  $t$  of European put and call options struck at  $K$  and expiring at  $T$ .

Therefore, we employ a methodology that is similar to that of Carr and Wu (2009). Assume we want to synthetically create a 60 day variance swap. On each trading day, we obtain and sort all out-of-the-money (OTM) options by time to maturity. We identify the two maturities  $T_1$  and  $T_2$  that are closest to and cover a time to maturity of 60 days. We retain options of maturities  $T_1$  and  $T_2$  only. As in previous studies, e.g. Jiang and Tian (2005) and Carr and Wu (2009), we truncate the first and second integrals in Equation (3)

---

<sup>4</sup>See Demeterfi et al. (1999) for an excellent treatment of the replicating strategy.

<sup>5</sup>The replication strategy is exact under the assumption that the underlying follows a continuous process only. However, jumps introduce an approximation error in the replicating strategy. The numerical analysis of Carr and Wu (2009) indicates that these errors are empirically small. Building on a recent result by Rompolis and Tzavalis (2013), we demonstrate that our main results are robust to the impact of jumps. See Section 3.5.4 for further details.

at  $K_l$  and  $K_u$  respectively:<sup>6</sup>

$$K_l = F_{t,T} \exp^{-10\sigma \frac{T-t}{365}} \quad (4)$$

$$K_u = F_{t,T} \exp^{10\sigma \frac{T-t}{365}} \quad (5)$$

where  $K_l$  and  $K_u$  refer to the lower and higher truncated strikes.  $\sigma$  is the average annualized implied volatility of all OTM options. All other variables are as previously defined. For each maturity, we obtain a grid of 1,000 equidistant implied volatilities for strikes between  $K_u$  and  $K_l$ . We linearly interpolate available Black (1976) implied volatilities across moneyness.<sup>7</sup> For strikes higher (lower) than the highest (lowest) listed strike price but lower (higher) than  $K_u$  ( $K_l$ ), we assume constant implied volatility.

We then convert implied volatilities back into option prices using the Black (1976) option pricing formula. We evaluate the integrands at each of the 1,000 points and numerically approximate (trapezoidal rule) the integrals in Equation (3) to estimate the variance swap rate. Finally, we linearly interpolate between the two swap rates to obtain the 60 day variance swap rate. We repeat the above steps every day to obtain time series of 60 day variance swap rates.

Consistent with the literature, we estimate realized variance as follows:<sup>8</sup>

$$RV_{t,T} = \frac{365}{30} \sum_{i=t+1}^T \left( \log \frac{F_{i,T}}{F_{i-1,T}} \right)^2 \quad (6)$$

---

<sup>6</sup>Our results are robust to the choice of truncation points. See Section 3.5.3 for further details.

<sup>7</sup>Section 3.5.2 shows that working with a spline interpolation approach yields very similar results.

<sup>8</sup>In essence, we study the "realized" variance risk premium. Section 3.5.1 analyzes the "ex-ante" variance risk premium. To do so, we use historical variance as a proxy for the floating leg of a variance swap. This does not affect our main findings.

where  $T$  is the maturity date of the variance swap,  $F_{i,T}$  denotes the futures contract observed at time  $i$  and expiring at time  $T$ .<sup>9</sup>

## 2.2 Data

We obtain our futures and option data from the Commodity Research Bureau (CRB). The data set contains information on the strike price, maturity and settlement price of individual commodity derivatives. Table 1 introduces the 21 commodities included in our sample. Our data includes commodities from a broad range of sectors, ranging from energy to wood commodities. The last column reports the average annual trading volume of individual commodity options for the years 2010 and 2011. We extract this information from the volume reports published on the exchange’s websites.<sup>10</sup> Generally, we see higher trading volume in some energy, grains and metal commodities than in other commodity sectors.

To mitigate the effect of micro-structure related issues such as infrequent trading and stale prices, we only retain options with time-to-maturity of at least 12 days. We further delete options with prices lower than five times the minimum tick size reported in Table 1. Given that our data set comprises American options and that our estimation approach requires European option prices, we convert the American option prices into European prices by following the standard approach of Barone-Adesi and Whaley (1987).

Our empirical analysis focuses on variance swaps with maturity of 60 and 90 days. This

---

<sup>9</sup>Note that, contrary to individual equities, commodity options are written on futures contracts which life span is finite. We base our computation of realized variance on constant maturity futures contracts (maturing in 60 and 90 days), which are obtained by linear interpolation of neighbouring futures.

<sup>10</sup>Ideally, one should report the average annual open interest and trading volume for the full sample period. Alas, the CRB does not provide such information. Fortunately, the exchanges recently started reporting volume data. We use the option trading volume for the period 2010–2011 as an indication of trading activity in commodity markets. Section 3.5.6 establishes the robustness of our findings to tradability concerns.

decision is motivated by the observation that, with the exception of energy markets, no other commodity exhibits a monthly expiration schedule (see Table 1). Since monthly variance swaps cannot be replicated, we focus on maturities of 60 and 90 days. Therefore, we retain only OTM options on the first two futures contracts. For energy commodities, we retain OTM options on the second and third futures contracts.<sup>11</sup> Table 2 provides an overview of the final data set of option prices. It shows that our sample period spans more than 20 years including the recent financial crisis. The last two columns report the average number of OTM call and put options per trading day. Across all commodities, there are on average 17 and 14 OTM call and put options with different strike prices per day, respectively. These numbers compare well with other studies such as those of Carr and Wu (2009) and Taylor et al. (2010).

### 3 Empirical Results

Prior to discussing our empirical results, it is instructive to visualize the time series dynamics of annualized realized variance (RV) and model-free implied variance (MFIV). Figure 1 plots these series for 6 commodities drawn from different sectors. This figure highlights several interesting features. First, RV and MFIV trend together. Second, MFIV is usually higher than RV, suggesting that short variance swaps investments are profitable. However, by visually inspecting these plots, it is difficult to ascertain whether these profits are significantly different from zero or whether similar results are obtained for other commodities. We elaborate on each of the above observations in the ensuing paragraphs.

---

<sup>11</sup>The reason for selecting the second and third nearby futures contracts is that, unlike other commodities, energy commodities have a monthly expiration schedule.

## 3.1 Is Variance Risk Priced in Commodity Markets?

We start our empirical analysis by ascertaining whether variance risk is priced in commodity markets. For each day in our sample, we compute the pay-off of variance swaps. If variance risk is priced, we expect the average pay-off to variance swaps to be of economically large magnitude and statistically significant.

### 3.1.1 Variance Swap Payoffs

Table 3 presents summary statistics of daily commodity variance risk premia. We can see that 60 day variance risk premia (see Panel A) are mainly negative, suggesting that variance risk is negatively priced in commodity markets. To assess the significance of variance risk premia, we report Newey-West t-statistics in the fourth column of Table 3.<sup>12</sup> The evidence for 60 day variance risk premia (Panel A) suggests that variance swaps generate statistically and economically significant pay-offs in virtually all markets.

The volatility of 60 day variance risk premia is generally low, with values usually below 7%. However, natural gas and coffee variance risk premia exhibit volatilities that are an order of magnitude higher (15% and 17%, respectively). The high volatility of silver's variance risk premium may well explain why its market price of variance risk is not statistically different from zero. Examining the higher moments of variance risk premia, we find evidence of positive skewness which contrasts with the negative skewness often found in returns. This observation indicates that, though short variance swap positions earn statistically and economically significant profits, these strategies could incur severe losses. Variance risk

---

<sup>12</sup>As is standard in the literature on variance risk premia, we account for the overlap among variance swaps by using Newey–West corrected standard errors. Section 3.5.8 repeats our analysis in a non-overlapping setting and shows that our main findings are robust to this concern.

premia are leptokurtic with kurtosis up to 24.48.

To gain insights into the term-structure of variance risk premia, we repeat the above analysis for 90 day variance risk premia and present the results in Panel B of Table 3. Generally, we observe significantly negative variance swap payoffs in most markets, thus confirming that variance risk is consistently negatively priced at both horizons.

In summary, Table 3 unequivocally points to significantly negative variance risk premia in most commodity markets. Interestingly, our evidence of significant variance risk premia for most commodities differs from that of individual equities reported in Carr and Wu (2009) and Driessen et al. (2009), highlighting the importance of a comprehensive analysis of variance risk across different asset classes.

### 3.1.2 Variance Swap Returns

To better appreciate the profitability of variance swap contracts, we compute the Log Variance Risk Premium (LVRP) defined as the continuously compounded excess return on a fully collateralized variance swap position. More formally, the variance swap return for the period from time  $t$  to  $T$  is computed as follows:  $LVRP_{t,T} = \log \left[ \frac{RV_{t,T}}{MFIV_{t,T}} \right]$ .

Panel A of Table 4 reports estimates that are mostly negative.<sup>13</sup> The standard deviation of LVRPs is fairly homogeneous across commodities with values typically below 50%. To better appreciate the risk/reward characteristics of commodity variance swaps, we report absolute values of annualized, Newey-West corrected Sharpe Ratios (SR) in the penultimate

---

<sup>13</sup>It is important to stress that under the null of zero variance risk premium, the average LVRP will be biased towards negative values due to Jensen's inequality. This observation explains the seemingly conflicting evidence, reported in Carr and Wu (2009), of significantly negative mean LVRP even though the average VRP, itself, is not statistically different from zero. Driessen et al. (2009) echo a similar concern in their footnote 13.

column of Table 4. We present absolute (rather than the predominantly negative) values of SR to facilitate the interpretation of the results. Table 4 demonstrates that 60 day commodity variance swaps yield sizable SR varying between 9.4% and 63.4%.<sup>14</sup> Clearly, these figures are higher than the 10% that a long passive investment in commodity futures typically generates (Kojien et al., 2012). The variability in SR within and across sectors is striking. At 2 month horizons, SR fluctuate between 34% and 47% in energy markets. This variability carries over to grains and livestock. For example, a short variance swap position in live cattle earns an annualized SR of 50.2%, almost three times higher than the 17.4% of lean hogs.

Similarly, Panel B of Table 4 reports SR that are higher than the reward to variability ratio of a passive investment in commodity futures. However, it is worth noticing that these SR are generally lower than those presented in Panel A, indicating a downward sloping term structure of SR.

## 3.2 Time Variation in Variance Risk Premia

In the following paragraphs, we analyze time variations in variance risk premia. First, we investigate the extent to which variance risk premia are predictable using current estimates of variance. Second, we investigate whether our findings of variance risk premia are driven by specific sample periods.

---

<sup>14</sup>In comparison, Carr and Wu (2009) report SR that vary between 0% and 55% for individual US equities.

### 3.2.1 Are Variance Risk Premia Predictable?

We begin by investigating whether variance risk premia are linearly related to current estimates of variance, thus shedding a revealing light on the extent to which variance risk premia are predictable. This is important for an investor who would like to time the variance swap market. Carr and Wu (2009) and Trolle and Schwartz (2010), investigate a similar question by estimating a regression of the form:<sup>15</sup>

$$RV_{t,T} - MFIV_{t,T} = \alpha + \beta MFIV_{t,T} + \epsilon. \quad (7)$$

Although intuitive, this model can be criticized on several grounds.<sup>16</sup> The regression is likely to yield a biased slope estimate since the MFIV appears on both sides of the equation. A simple way to tackle this problem consists in using historical variance rather than option implied variance as the independent variable. Still, this does not address the potentially more serious issue of unbalanced regression. Indeed, Equation (7) is likely to be an imbalanced regression since the order of integration of the dependent variable is much smaller than that of the independent variable.<sup>17</sup> To address this issue, we draw on the arguments of Bollerslev et al. (2013) and regress the variance risk premium on the fractionally differenced historical variance (*HIST*):

$$RV_{t,T} - MFIV_{t,T} = \tilde{\alpha} + \tilde{\beta} HIST_t + \epsilon. \quad (8)$$

where  $RV_{t,T}$  is the realized variance between times  $t$  and  $T$ .  $MFIV_{t,T}$  is the model-free

---

<sup>15</sup>It is straightforward to rearrange the regression models presented in Carr and Wu (2009) and Trolle and Schwartz (2010) to obtain Equation (7).

<sup>16</sup>We are grateful to Natalia Sizova for pointing these issues to us.

<sup>17</sup>Note that the dependent variable is the difference of two series, making its order of integration smaller than that of the original series.

implied variance between times  $t$  and  $T$ .  $HIST_t$  is the fractionally differenced historical variance. As is standard in the literature, we set the order of fractional integration at 0.40.

The first five columns of Table 5 report the results from the regression represented in Equation (8). If variance risk premia are predictable, we expect to see a slope estimate that is significantly different from zero. Starting with 60 day variance risk premia, we find that the slope estimates are generally not statistically distinguishable from zero. This result suggests that commodity variance risk premia are unrelated to historical variance. We also assess whether variance swap returns are predictable by estimating the following regression:

$$\log(RV_{t,T}) - \log(MFIV_{t,T}) = \hat{\alpha} + \hat{\beta} \log(HIST_t) + \epsilon. \quad (9)$$

where  $\log(RV_{t,T})$  is the log realized variance between times  $t$  and  $T$ .  $\log(MFIV_{t,T})$  is the log model-free implied variance between times  $t$  and  $T$ .  $\log(HIST_t)$  is the (fractionally) differenced logarithm of historical variance. The last five columns report the coefficients, t-statistics and  $R^2$  of the above regression. The main findings do not change: variance swap returns are generally unpredictable. Similar conclusions emerge from Panel B.

Overall, our results suggest that the market price of commodity variance risk is not predictable by historical variance. Thus, an investor would not be able to use historical variance to successfully time variance swap investments. It is worth noticing that our conclusion differs from that of Carr and Wu (2009) and Trolle and Schwartz (2010), who find some evidence of predictability. We attribute the difference in results to our robust econometric approach that allows us to address the statistical issues discussed above, thus guarding

ourselves against spurious predictability.<sup>18</sup>

### 3.2.2 Is Variance Risk a Recent Phenomenon?

In light of the recent debates on the financialization of commodity markets, one may naturally wonder whether the pricing of variance risk is a recent phenomenon brought about by the financialization of commodity markets. We address this important question by studying variance risk premia during two distinct periods: the first period runs through November 2004, the second subsample starts from December 2004 onward.<sup>19</sup> These periods are selected because of their economic importance. The first subsample, which we refer to as “pre-financialization”, corresponds to a period of low investor participation in commodity markets. The second period coincides with the financialization of commodity markets, a period characterized by increased investor flows into commodities.

Table 6 establishes that variance risk is significantly priced in commodity markets during each of the two periods analyzed. Our results point to consistently negative variance risk premia for most markets. This is true for each period. Moreover, for each commodity market, the variance risk premia estimates are of similar order of magnitude in each of the two subsamples. Collectively, these results show that variance risk premia are fairly consistent by commodity, and consistently negative overall, in both sample periods. Thus, we conclude that our findings of significant variance risk premia are not driven by a specific period. Quite the contrary, there are sizable variance risk premia in commodity markets

---

<sup>18</sup>In an earlier draft of this paper, we follow the steps outlined in Carr and Wu (2009) and Trolle and Schwartz (2010). Their approach, which suffers from the concerns previously discussed, leads us to the conclusion that variance risk premia are predictable. The details of this analysis are not reported for brevity.

<sup>19</sup>In a recent study, Hamilton and Wu (2014) document a structural break in commodity futures risk premia in December 2004. Other studies suggest 2005 as a breakpoint. Considering 2005 as a breakpoint leads to very similar results. These results are not reported for brevity.

both during the “pre-financialization” and “financialization” sample periods.

These findings have a more profound implication. In particular, they suggest that liquidity effects are unlikely to drive our results. This is because the second sample period relates to a period of high trading activity in commodity markets. If liquidity drove our results, one would observe marked differences across both sample periods. However, our analysis establishes that the results for the two samples are broadly similar, making liquidity-based explanations difficult to reconcile with the data. Section 3.5.6 digs deeper into the issue of liquidity and presents a variety of analyses that further establish the robustness of our findings.

### **3.3 Commonalities in Variance Swap Returns**

We now investigate commonalities in variance swap returns. Understanding the factor structure of commodity variance risk premia is important for investors. In particular, if commodity variance risk premia are largely orthogonal to each other, then there may be important diversification benefits to be gained by combining all variance swaps into a portfolio. Furthermore, exploring the comovement between commodity variance swaps and equity variance swaps during the “pre-financialization” and “financialization” periods provides valuable insights into the impact of the financialization of commodity markets. We begin by analyzing the correlations across commodities. We then study comovements across asset classes.

#### **3.3.1 Evidence from Commodity Markets**

Panel A of Table 7 presents the average correlation within each commodity sector. These figures are computed as follows. For each sector, e.g. energy, we compute pair-wise cor-

relations between the variance swap returns of constituent commodities. We then average all pair-wise correlations to obtain the correlation within a sector. Note that we do not perform this analysis for the wood sector because it contains only one commodity (lumber). The correlation estimates vary between 5.68 % (tropical) and 33.42 % (energy) for 60 day variance swap returns, indicating mild comovements within sectors. Similarly, the average correlations of 90 day variance swap returns fluctuate between 11.48 % (tropical) and 33.05 % (metals). In general, these coefficients point to moderate commonalities within commodity sectors.

We now extend our analysis by studying commonalities across (rather than within) commodity sectors. Each trading day, we compute the return on an equally-weighted portfolio of variance swaps of all commodities involved in a specific sector. By doing so, we obtain time series of variance swap returns for each sector. Next, we compute pair-wise correlations across different sectors. Panels B and C of Table 7 report moderate correlations across sectors. Generally, the reported figures vary from 6.54 % (livestock and metals) to 24.65 %, (grains and tropicals) at the shorter horizon.<sup>20</sup>

The relatively moderate correlations across commodity variance swap returns suggest that a diversified portfolio of commodity variance swaps might have desirable characteristics. We verify this by computing the, Newey-West corrected, annualized SR of a portfolio of variance swaps. Each day, we take an equally-weighted short position in all available variance swaps of a specific maturity. Since we do not have options data for most commodities in the year 1989, we construct the diversified portfolio from 1990 onward. On average, the diversified

---

<sup>20</sup>We also perform a principal component analysis (PCA). The results, not reported here for brevity, suggest that five factors are necessary to explain variations in variance swap returns across sectors with each factor capturing roughly 20 % of common variations.

portfolio comprises 15 commodity markets. Focusing on the row labelled “Diversified” in Table 4, we can see that a short equally-weighted portfolio of commodity variance swaps generates returns of 21.1% and 19% at the 60 and 90 day horizon, respectively. The short diversified portfolio performs well compared to short individual commodity variance swaps as its reward to variability ratio is equal to 37.9% and 23.6% for the shorter and longer maturities, respectively.

### 3.3.2 Evidence from Equity and Bond Markets

We also analyze comovements between commodity, equity and Treasury variance swap returns. To this end, we use options data on the S&P 500 index and the 30-Year US Treasury bond. Our data comes from OptionMetrics and starts from 1996.<sup>21</sup> We follow the steps outlined in Section 2 to estimate the variance risk premia of these markets.<sup>22</sup> We then compute the pair-wise correlations between the variance swap returns of individual commodity sectors and those of the stock and bond markets. Rows “S&P 500” and “Treasury” of Table 7 highlight moderate comovements between bond and equity variance swap returns on the one hand and commodity variance swap returns on the other. For example, the correlation between energy and equity (bond) variance swap returns is 26.50% (20.18%) at the bimonthly

---

<sup>21</sup>Our sample period for the S&P 500 and Treasury markets is determined by the availability of data from OptionMetrics. The sample period for the bond and equity markets is shorter than that of most commodities. One should bear this in mind when interpreting our results.

<sup>22</sup>The last two rows of Tables 3 and 4 report summary statistics of bond and equity variance and log variance risk premia, respectively. Briefly, we can see that variance risk is negatively priced in both markets. This is true for both the short and long horizons. More interestingly, a short position in S&P 500 variance swaps yields an annual reward to variability ratio of around 37%. This is important for two reasons. First, it indicates that a portfolio of short commodity variance swaps earns a Sharpe Ratio that is very similar to that of a short position in the S&P 500 variance swap. Moreover, the Sharpe Ratio of the short S&P 500 variance swap position is substantially smaller than the 0.98 documented by Carr and Wu (2009) at the monthly horizon. While this result may be due to a downward sloping term-structure of variance risk premia, it could also highlight the importance of analyzing variance swaps over a long period to draw robust inferences.

horizon.

Motivated by the literature on the financialization of commodities, we analyze how the markets comove during different time periods. To this end, we repeat our analysis for each of the two regimes discussed in Section 3.2.2. Table 8 uncovers important differences between the two time periods. For example, the correlation between 60-day energy and equity variance risk premia is low (2.62 %) during the first sub period (see Panel A). However, it soars to 47.50 % in the second subsample (see Panel C). More generally, we can clearly see that variance swap returns are strongly correlated with each other during the “financialization” subsample. This stylized fact amounts to direct and model-free evidence that the financialization of commodity markets documented by Tang and Xiong (2012) affects not only the risk premia associated with the first but also the second moment of commodity returns.

Overall, we find some commonalities in variance swap returns across asset classes. Our results show that commodity variance swap returns are increasingly integrated with those of the bond and equity markets, indicating that the financialization of commodity markets is a general phenomenon that affects not only price risk premia but also variance risk premia.

### 3.4 Price v.s. Variance Risk Premia

We now turn our attention to the relationship between *price* and *variance* risk premia. First, we examine the connection between equity and bond risk premia on the one hand and commodity variance risk premia on the other. This analysis is important to understand the sources of risk that drive commodity variance risk premia. For example, if commodity variance risk premia load on the macroeconomic factors of Ludvigson and Ng (2009), we

would conclude that commodity variance risk represents a compensation for macroeconomic risk. Second, we focus on the link between the variance swap returns of a commodity and its own futures returns. This allows us to ascertain whether commodity variance risk is fundamentally different from futures risk in the sense that the drivers of commodity returns do not affect variance swap returns. This analysis also has important implications for models that are needed to capture the dynamics of commodity markets. If variance risk is orthogonal to futures risk, it may be that models with unspanned stochastic volatility are needed to capture the rich dynamics of commodity markets.

### 3.4.1 Equity Risk Premia

It is natural to wonder whether variance swap returns are linked to the systematic factors that drive equity risk premia. For instance, the negative sign of the market price of variance risk may be consistent with the Capital Asset Pricing Model (CAPM) and its extensions. If an asset's volatility is negatively related to the market return, as is the case in equities, then one would expect a negative variance risk premium.

To investigate this possibility, we analyze the relationship between variance swap returns and the 3 factors of Fama and French (1993). We obtain our data from French website and estimate the following regression for each commodity:

$$LVRP_t = \alpha + \beta MKT_t + \gamma SMB_t + \delta HML_t + \epsilon_t. \quad (10)$$

where  $LVRP$ ,  $MKT$ ,  $SMB$  and  $HML$  denote the time series of variance swap returns, the market, small minus big and high minus low factors, respectively.

Tables 9–10 mostly report insignificant slope estimates, which indicate that commodity variance swap returns are largely orthogonal to the determinants of equity returns. Furthermore, the three factors typically account for less than 1% of variations in commodity variance swap returns, leading us to conclude that commodity variance swap returns cannot be satisfactorily explained by the Fama and French (1993) factors.

### 3.4.2 Bond Risk Premia

We now investigate how commodity variance swap returns relate to the determinants of bond risk premia. We draw upon the work of Ludvigson and Ng (2009), who implement a dynamic factor analysis decomposition to extract 8 factors from a panel of 132 macroeconomic variables. We also use the Cochrane and Piazzesi (2005) factor, which has been shown to capture bond risk premia. All data are downloaded from Ludvigson’s website.

Table 11 presents the results of regressions of 60 day variance risk premia on these factors. On average, the regression yields very low explanatory power, signaling that commodity variance swap returns are not affected by the drivers of bond risk premia. Moreover, the slope coefficients are of very low magnitude, with each factor exhibiting little statistical significance. We obtain similar results for variance swaps of 90 day maturity (see Table 12). Evidently, commodity variance swap returns are different from bond risk premia.

### 3.4.3 Commodity Price Risk Premia

To analyze the relationship between commodity variance risk premia and commodity price risk premia, we regress variance swap returns on futures returns computed as follows

$$RET_{t,T} = \frac{365}{30} \sum_{i=t+1}^T \log \frac{F_{i,T}}{F_{i-1,T}} \quad (11)$$

where all variables are as previously defined.<sup>23,24</sup>

If price and variance risk premia are strongly related, we expect to see a high explanatory power and significant slope estimates. Conversely, a weak relationship between the two risk premia would suggest that variance risk is unspanned by a single futures contract. Table 13 displays statistically significant intercept estimates in all markets. More importantly, the intercepts are remarkably similar to the unconditional variance swap returns presented in Table 4. Generally, we also observe low explanatory power and predominantly insignificant slope estimates, indicating a weak relationship between price and variance risk premia.

This analysis provides model-free evidence of unspanned stochastic variance in commodity markets: stochastic variance is not spanned by a long position in a single futures contract. A direct implication of this result is that term structure models of commodity futures must allow for both spanned and unspanned stochastic variance. In future work, it would be interesting to dig deeper into this class of models. Trolle and Schwartz (2009) provide an

---

<sup>23</sup>Including the Goldman Sachs Commodity Index (GSCI) in our regression model does not materially affect our results. These are not reported for brevity.

<sup>24</sup>An alternative approach consists in identifying and using factors that explain variations in commodity futures returns. Alas, it is not entirely clear which factors (if any) successfully price commodity futures returns (Daskalaki et al., 2014; Szymanowska et al., 2014). Our direct approach, which broadly mirrors that of the literature on unspanned stochastic volatility, allows us to conveniently sidestep this fiercely debated issue by directly using commodity futures risk premia in the regression model.

interesting starting point.

### 3.5 Robustness Analysis

In this section, we establish the robustness of our findings. To begin with, we demonstrate that our main results hold when we analyze the expected (as opposed to realized) market price of variance risk. Next, we show that our findings are robust to the interpolation technique. We then confirm that the choice of truncation points does not materially affect our main results. Subsequently, we demonstrate that our approach yields implied volatility indices that correlate very well with (the handful of) publicly available volatility indices. Additionally, we demonstrate that our main findings are robust to liquidity-based explanations. Moreover, we analyze the impact of seasonality on our core results. Lastly, we repeat our analysis using non-overlapping data and confirm that our main results hold.

#### 3.5.1 Expected Variance Risk Premia

Although consistent with the market definition of variance swap payoffs, it is important to acknowledge that our estimates of variance risk premia implicitly assume that realized variance is equal to the physical expectation of variance. Strictly speaking the variance risk premium is equal to the difference between the physical and risk-neutral expectations of variance. Viewing realized variance as the sum of the physical expectation of variance plus a shock, our finding of negative variance risk premia could be taken as evidence that the mean shock is negative. Thus, it appears important to also analyze the *expected* market price of variance risk.

Following Bollerslev et al. (2009), we use historical (rather than realized) variance as the

floating leg of our variance swap and repeat our analysis. Before discussing the results of this exercise, it is important to stress that the analysis assumes that investors use historical variance to form their expectation about future variance, making the results somewhat model dependent.<sup>25</sup> In a recent study, Bekaert and Hoerova (2014) provide a detailed discussion of this issue and warn that findings based on expected (as opposed to realized) variance risk premia must be interpreted cautiously.

Tables 14 and 15 present the results of this analysis. Typically, expected and realized variance swap returns display a correlation coefficient that is mainly positive. More important, our analysis reveals that investors expect significantly negative variance risk premia in most commodity markets. This result holds for both maturities and is similar to our original conclusion.

### **3.5.2 Interpolation Technique**

We evaluate the robustness of our results to the interpolation technique. To this end, we follow the procedure outlined in Section 2 with one difference: we use a cubic spline (rather than linear) interpolation technique to obtain a fine grid of implied volatilities. Tables 16 and 17 demonstrate that our results are robust to the interpolation technique. In particular, Column "Corr" shows that the variance risk premia obtained using the spline and linear interpolation techniques are strongly related with correlation coefficients typically greater than 99.9%. Our main conclusions are unchanged: commodity variance risk premia are significantly negative and of economically large magnitude.

---

<sup>25</sup>It is beyond the scope of this paper to identify the best forecasting model of variance. See Andersen et al. (2009) for a recent survey of the literature on variance forecasting.

### 3.5.3 Truncation Points

We also investigate the sensitivity of our variance swap estimates to the truncation points.

We work with tighter truncation points,  $K_l$  and  $K_u$ , defined as follows:

$$K_l = F_{t,T} \exp^{-8\sigma \frac{T-t}{365}} \quad (12)$$

$$K_u = F_{t,T} \exp^{8\sigma \frac{T-t}{365}} \quad (13)$$

where all variables are as previously explained.

As Tables 18 and 19 clearly show, our results are not materially affected by this change. In fact, "Corr" reveals that the correlation between the newly estimated variance risk premia and our benchmark estimates is typically greater than 99.9%, demonstrating that our results are not affected by the choice of truncation points.

### 3.5.4 The Role of Jumps

We now examine the robustness of our results to jumps, which could affect the replication of variance swap rates. In a recent study, Rompolis and Tzavalis (2013) formally prove that the

bias due to jumps (JB) is related to the model-free skewness (MFS) and kurtosis (MFK):

$$JB_{t,T} = 365 \times \frac{-2e^{r_t \frac{T-t}{365}}}{T-t} \left[ \frac{1}{3!} MFS_{t,T} + \frac{1}{4!} MFK_{t,T} \right] \quad (14)$$

$$MFS_{t,T} = \int_{F_{t,T}}^{+\infty} \frac{6 \log[\frac{K}{F_{t,T}}] - 3 (\log[\frac{K}{F_{t,T}}])^2}{K^2} C(t, K, T) dK \\ - \int_0^{F_{t,T}} \frac{6 \log[\frac{K}{F_{t,T}}] + 3 (\log[\frac{K}{F_{t,T}}])^2}{K^2} P(t, K, T) dK \quad (15)$$

$$MFK_{t,T} = \int_{F_{t,T}}^{+\infty} \frac{12 (\log[\frac{K}{F_{t,T}}])^2 - 4 (\log[\frac{K}{F_{t,T}}])^3}{K^2} C(t, K, T) dK \\ - \int_0^{F_{t,T}} \frac{12 (\log[\frac{K}{F_{t,T}}])^2 + 4 (\log[\frac{K}{F_{t,T}}])^3}{K^2} P(t, K, T) dK \quad (16)$$

where  $JB_{t,T}$  refers to the bias due to jumps.  $MFS_{t,T}$  and  $MFK_{t,T}$  denote the model-free skewness and kurtosis, respectively. All other variables are as previously defined.

Following Rompolis and Tzavalis, we add together the MFIV and the JB to obtain a jump robust estimate of the risk-neutral expectation of variance. We then repeat our analysis of variance risk premia and variance swap returns. Tables 20 and 21 demonstrate that accounting for the role of jumps does not change our main findings. While the absolute level of our variance risk premia estimates decreases, we still find statistically significant and negative variance risk premia in most markets, strengthening the conclusion that short variance swap positions are highly profitable in commodity markets.

### 3.5.5 Synthetic v.s. Public Volatility Indices

We compare our synthetic swap rates to publicly available volatility indices. Since our methodology broadly mirrors that of the exchange, we expect the synthetic and publicly available variance swap rates to be highly correlated. Although there are volatility indices

for the corn, soybeans and wheat markets, these indices were only recently introduced. Hence, we focus only on the crude oil and gold markets. There are, however, 2 issues that need to be highlighted. First, the crude oil volatility index reported by the exchange is based on a 30 day horizon. In contrast, our synthetic variance swap rates are available for horizons of both 60 and 90 days. To ensure a valid comparison, we create synthetic variance swaps of 30 days for the crude oil market.<sup>26</sup> These variance swaps are used solely for comparison purposes and are not discussed further in the paper. Second, the exchange lists the model-free implied volatility rather than variance. As a result, we square the volatility indices in order to make them comparable to our variance swap rates.

The comparison period extends from May 11, 2007 to September 2, 2011 for crude oil. Similarly, the period of interest starts from September 13, 2010 to August 10, 2011 for gold. Overall, the overlapping periods comprise 1078 and 227 days for the crude oil and gold markets, respectively. First, we compute the correlation between our synthetic variance swap rates and the CME series. As expected, we observe a high correlation between the two series. The correlation coefficients are equal to 97.38 % and 98.04 % for the crude oil and gold markets, respectively. Second, we analyze the mean difference and find that our synthetic variance swap rate is very close to its CME counterpart. For example, the synthetic swap rate of gold differs from that of the exchange by an average of 11 basis points. Together, these results confirm the robustness of our methodology.

---

<sup>26</sup>As discussed before, the construction of monthly variance swaps is not possible for non-energy commodities. This is due to the fact that non-energy commodity options do not have monthly expiration cycles.

### 3.5.6 Tradability of Commodity Variance Swaps

Studies on variance risk premia, including those of Carr and Wu (2009) and Driessen et al. (2009), are invariably criticized on the grounds that option contracts may not be actively traded and this may significantly drive the results. We argue that this is unlikely to be true in our case for several reasons. First, the evidence of significantly negative variance risk premia is not specific to a limited number of commodity markets. Rather this finding holds for virtually all commodity markets, making a liquidity-based explanation of our results very challenging. Second, if the lack of liquidity significantly drove our results, one would observe large differences in the magnitude, sign, and statistical significance of the variance risk premia during the “financialization” period, when commodities witnessed a surge in trading activity. However, as Table 6 clearly shows, the sign and magnitude of commodity variance risk premia is stable across both the “pre-financialization” and “financialization” samples, making our results difficult to reconcile with a liquidity-based argument.

Another potential concern is that the performance of the diversified portfolio of commodity variance swaps is difficult to achieve in practice because it includes less actively traded commodity markets. To address this concern, we construct an equally-weighted portfolio of commodity variance swaps that includes only the 7 most actively traded commodities. To identify these actively traded commodities, we use the average yearly option trading volume reported in Table 1.<sup>27</sup> The seven markets are corn, crude oil, gold, natural gas, soybeans,

---

<sup>27</sup>To a large extent, the decision to look at the option trading volume for the period 2010–2011 is forced upon us, as the CRB data set does not contain information on the trading volume of individual options. As a further robustness check, we obtain the average yearly futures trading volume for the period 1989–2011 from Bloomberg. We then create another portfolio that includes the 7 commodities with the highest average futures (rather than option) trading volume and obtain very similar results. This is hardly surprising because 6 (of the 7) commodity markets with the highest average option volume are also among the 7 markets with the highest average futures trading volume.

sugar and wheat. Our unreported analysis shows that the newly constructed portfolio yields SR equal to 36.01% and 17.04% for the shorter and longer horizons, respectively. Overall, these reward-to-variability ratios are very similar to those reported for the unrestricted portfolio of commodity variance swaps (see Table 4). The upshot of this is that our main findings are robust to liquidity concerns.

One may also wonder about the impact of transaction costs on our variance risk premia estimates. It may be that our synthetic variance swap rates are the sum of the true variance swap rates and transaction costs. It is therefore possible that the variance risk premia estimates presented in Table 3 are biased downwards, i.e. more negative than the true variance risk premia, owing to the influence of transaction costs. To investigate this, we incorporate transaction costs in our analysis. We follow two approaches. First, we assume that transaction costs represent a proportion of 5% of the synthetic variance swap rate. This implies that the true variance swap rate corresponds to 95% of the synthetic variance swap rate. For example, if the synthetic variance swap rate is 10% the true variance swap rate is 9.5%. Second, we allow for fixed transaction costs in the spirit of Duarte et al. (2007), by assuming that the true model-free implied volatility (not variance) is, in level terms, 1% lower than the synthetic model-free implied volatility. This means that if the synthetic model-free implied volatility is 10%, then the true implied volatility is 9%, leading to a true variance swap rate of 0.81%. It is worth noticing that this approach is generally more stringent than the proportional approach, thus yielding very conservative variance risk premia estimates. Tables 22–23 summarize our main results. Although we observe slightly less negative variance risk premia for most markets, we can see that most variance risk premia remain significantly negative. This is true regardless of whether we assume proportional or

fixed transaction costs.<sup>28</sup> Collectively, these analyses indicate that our results are not driven by the effect of transaction costs.

### 3.5.7 Seasonality in Commodity Variance Swap Returns

Many commodities exhibit seasonal patterns. Suenaga et al. (2008) document the seasonality of realized variance in the natural gas market. More recently, Back et al. (2013) find evidence of seasonality in implied volatilities. One may wonder how this salient feature of commodity markets affects our analysis of commonalities.

To address this concern, we deseasonalize variance swap returns by regressing individual series on twelve monthly dummies. We then use the deseasonalized series to repeat all our analyses. Focusing on our investigation of commonalities across markets, Table 24 reports similar results to our baseline estimates (see Table 7). Clearly, accounting for calendar variations in commodity variance swap returns does not materially affect our results.

### 3.5.8 Non-Overlapping Samples

Although the various statistics displayed in Table 3 are compelling, they are subject to the criticism that we estimate variance on a rolling window basis, thus introducing a moving average structure in our analysis. Although we account for this autocorrelation by using robust standard errors, one may want to repeat the analysis in a non-overlapping setting.

Table 25 highlights a noticeable reduction in the autocorrelation of variance risk premia.

For example, the autocorrelation of gold's 60 day variance risk premium falls from 0.97 to

---

<sup>28</sup>We go a step further and assume that the manager of a portfolio of short variance swaps charges performance fees equal to 20% of the payoff to variance swaps. This implies that the net-of-fees variance risk premia correspond to 80% of the figures reported under Tables 22–23. More importantly, the t-statistics of the net-of-performance-fees variance risk premia correspond to approximately  $0.9(\sqrt{0.8})$  of those shown in Tables 22–23. Clearly, the significance of our main findings is robust to this.

0.21. This is not surprising, given that there is no overlap between consecutive variance swap contracts. All other results are broadly consistent with those reported in Table 3: variance risk is significantly priced in commodity markets.

## 4 Conclusion

This paper investigates the market price of variance risk in 21 commodity markets from 1989 to 2011. Using synthetically constructed variance swaps, we present model-free evidence of variance risk premia in commodity markets. We document that variance risk is negatively priced in most commodity markets. A portfolio of short commodity variance swaps earns a large Sharpe ratio, highlighting the potential benefits of investing in variance derivatives. Our results hold for variance swap contracts that mature in either 60 or 90 days and we confirm that variance risk is priced during both the “pre-financialization” and “financialization” sample periods.

We uncover evidence of commonalities in variance swap returns both within and across commodity sectors. More important, our analysis reveals increasing comovements between commodity variance swap returns on the one hand and bond and equity variance swap returns on the other. This suggests that the financialization of commodity markets is not restricted to futures markets. Rather, it is a pervasive phenomenon that also affects the market for variance swaps.

Finally, we show that commodity variance risk premia are distinct from traditional risk premia. In particular, we establish that the Fama and French (1993) and the Ludvigson and Ng (2009) factors, which successfully capture equity and bond risk returns, cannot explain

commodity variance swap returns satisfactorily. Moreover, regressing commodity variance risk premia on price risk premia, we find that the two risk premia are distinct, suggesting that variance risk is unspanned by commodity futures.

**Figure 1: Time Series of Realized Variance and Model-Free Implied Variance**

*This figure displays the time series of realized and model-free implied variances for crude oil, wheat, live cattle, copper, cocoa and lumber over a 60 day horizon. The horizontal axis shows the dates. The vertical axis shows the annualized variance estimates (multiplied by 100). The blue and green lines represent model-free implied and realized variances, respectively. The difference between realized and implied variances is the variance risk premium.*

**Table 1: Overview of Commodities**

*This table lists all commodities considered. The first two columns report the sector and name of specific commodities. The third column displays the exchange where the futures and options contracts of the commodity are traded. The fourth and fifth columns report the available maturity months and minimum tick sizes of the underlying contracts as reported by the relevant exchange. The sixth column shows the contract size of each derivative contract. The last column displays the average yearly option volume (based on the years 2010 and 2011). We extract this information from the volume reports published on the exchange's websites.*

Sector	Commodity	Exchange	Maturity Months	Tick Size	Contract Size	Volume
<b>Energy</b>	Crude Oil	NYMEX	January-December	\$0.01 per barrel	1,000 barrels	35,901,515
	Heating Oil	NYMEX	January-December	\$0.0001 per gallon	42,000 gallons	891,918
	Natural Gas	NYMEX	January-December	\$0.001 per MMBtu	10,000 million British thermal units	25,995,473
<b>Grains</b>	Corn	CBOT	January, March, May, July, September, November, December	\$0.0025 per bushelÅ	5,000 bushels	28,650,380
	Cotton	ICE	March, May, July, October, December	\$0.0001 per pound	50,000 pounds net weight	2,853,173
	Soybeans	CBOT	January, March, May, July, August, September, November	\$0.0025 per bushelÅ	5,000 bushels	11,641,356
	Soybean Meal	CBOT	January, March, May, July, August, September, October, December	\$0.10 per short ton	100 short tons	984,277
	Soybean Oil	CBOT	January, March, May, July, August, September, October, December	\$0.0001 per pound	60,000 pounds	2,102,072
	Sugar	ICE	March, May, July, October, December	\$0.0001 per pound	112,000 poundsÅ	7,713,957
<b>Livestock</b>	Wheat	CBOT	March, May, July, September, December	\$0.0025 per bushelÅ	5,000 bushels	4,588,187
	Lean Hogs	CME	February, April, June, July, August, October, December	\$0.00025 per poundÅ	40,000 pounds	861,942
<b>Metals</b>	Live Cattle	CME	February, April, June, August, October, December	\$0.00025 per pound	40,000 pounds	2,551,210
	Copper	COMEX	February, April, June, August, October, December	\$0.0005 per pound	25,000 pounds	12,203
	Gold	COMEX	March, May, July, September, December	\$0.10 per troy ounce	100 troy ounces	8,905,621
	Silver	COMEX	March, May, July, September, December	\$0.001 per troy ounce	5,000 troy ounces	1,882,170
	Cocoa	ICE	March, May, July, September, December	\$1.00 per metric ton	10 metric tons	487,270
	Colombian Coffee	ICE	March, May, July, September, December	\$0.0005 per pound	37,500 pounds	2,464,992
<b>Tropical</b>	Oats	CBOT	March, May, July, September, December	\$0.0025 per bushelÅ	5,000 bushels	19,020
	Orange Juice	ICE	January, March, May, July, September, November	\$0.0005 per pound	15,000 poundsÅ	195,483
	Rough Rice	CBOT	January, March, May, July, September, November	\$0.005 per hundredweightÅ	2,000 hundredweights	37,770
<b>Wood</b>	Lumber	CME	January, March, May, July, September, November	\$0.10 per mbfÅ	110,000 nominal board feet	8,033

**Table 2: Description of Options Data**

*This table summarizes information about the OTM options data. The first two columns report the sector and name of specific commodities. Columns "Starting Date" and "Ending Date" indicate the beginning and end of the sample, respectively. "Days" reports the number of observation days in the sample. The last two columns show the average number of OTM calls and puts with different strike prices on each trading day, respectively.*

<b>Sector</b>	<b>Commodity</b>	<b>Starting Date</b>	<b>Ending Date</b>	<b>Days</b>	<b>Calls</b>	<b>Puts</b>
<b>Energy</b>	Crude Oil	January 16, 1989	September 2, 2011	5640	27	22
	Heating Oil	January 11, 1989	September 14, 2011	5660	29	24
	Natural Gas	October 2, 1992	September 14, 2011	4740	51	27
<b>Grains</b>	Corn	February 24, 1989	October 7, 2011	5691	19	13
	Cotton	January 30, 1990	November 16, 2007	4449	20	15
	Soybeans	February 24, 1989	October 7, 2011	5692	20	14

<b>Metals</b>	Copper	December 12, 1989	October 11, 2011	5461	12	14
	Gold	January 3, 1989	October 11, 2011	5704	16	13
	Silver	March 3, 1989	October 26, 2011	5673	24	32
<b>Tropical</b>	Cocoa	March 6, 1990	September 23, 2011	5384	10	6
	Colombian Coffee	March 5, 1990	September 30, 2011	5390	5	19
	Oats	May 1, 1990	August 12, 2011	5344	7	5
	Orange Juice	March 2, 1990	October 7, 2011	5370	8	4
<b>Wood</b>	Rough Rice	April 10, 1992	July 14 2011	4832	9	6
	Lumber	June 5, 1987	November 15, 2010	5680	10	7

**Table 3: Variance Risk Premia**

*This table presents summary statistics of the estimated commodity variance risk premia. Columns entitled Mean, T-Stat, Median, AR(1), Min and Max report the average, Newey-West corrected t-statistic (same lag length as the maturity of the swap), median, first order auto-correlation, minimum and maximum variance risk premia. The last four columns display the standard deviation, skewness, kurtosis and number of observations, respectively. Panel A presents the results for a horizon of 60 days, Panel B for a horizon of 90 days.*

**Panel A: 60 Day Variance risk premia**

**Table 5: Time Variation in Variance Risk Premia**

This table reports results from the regressions of variance risk premia on fractionally differenced historical variance.  $\tilde{\alpha}$  reports the intercept estimates and the corresponding  $t$ -statistics (in brackets). The  $t$ -statistics are adjusted following the method of Newey-West with lag length equal to the maturity of the variance swap.  $\tilde{\beta}$  reports the slope estimate and the corresponding  $t$ -statistic (in brackets). Columns  $\hat{\alpha}$  and  $\hat{\beta}$  present the analogous regression results for log variance risk premia.

**Panel A: 60 Day Variance Risk Premia**

**Table 7: Commonalities in Variance Swap Returns**

*This table summarizes the correlations of log variance risk premia within and across commodity sectors. In Panel A, we report the average pair-wise correlation across all commodities of the same family. For example, we calculate the pair-wise correlations between crude oil, heating oil and natural gas. We then compute the average of these correlations which we report under the appropriate sector: energy. Columns headed "60-Day" and "90-Day" indicate a maturity of 60 and 90 days, respectively. Panels B and C report correlations across different commodity sectors for variance swaps of maturity 60 and 90 days, respectively. For each sector and trading day, we calculate the return on an equally-weighted portfolio of variance swaps of all commodities belonging to that specific sector. After calculating the returns of each portfolio, we compute the pair-wise correlations of returns across sectors, which we present in Panels B and C.*

**Panel A: Commonalities Within Sector**

Sector	Correlation	
	60 Day	90 Day
Energy	33.42%	32.83%
Grains	24.19%	21.02%
Livestock	31.38%	20.07%
Metals	30.08%	33.05%
Tropical	5.68%	11.48%
Wood	—	—

**Panel B: Commonalities Across Sectors (60 Day)**

**Panel C: Commonalities Across Sectors (90 Day)**

Sector	Energy	Grains	Livestock	Metals	S&P500	Treasury	Tropical	Wood
Energy	100.00%							
Grains	8.17%	100.00%						
Livestock	11.69%	15.81%	100.00%					
Metals	24.23%	10.69%	-7.05%	100.00%				
S&P500	27.50%	6.57%	16.15%	32.30%	100.00%			
Treasury	21.38%	20.45%	-0.81%	11.90%	51.89%	100.00%		
Tropical	17.80%	33.87%	14.39%	13.54%	5.32%	-5.39%	100.00%	
Wood	16.33%	6.75%	10.41%	-3.44%	9.43%	15.91%	12.13%	100.00%

**Table 8: Time Varying Commonalities in Variance Swap Returns**

*This table summarizes the correlations of variance swap returns across different markets. For each commodity sector and trading day, we calculate the return on an equally-weighted portfolio of variance swaps of all commodities belonging to a specific sector. After calculating the returns of each portfolio, we compute the pair-wise correlations of returns across different sectors. We then compute the correlations between Energy, Grains, Livestock, Metals, S&P 500, Treasury, Tropical and Wood variance swap returns. We perform our analysis over two distinct periods. The pre-financialization period stops before December, 2004. The financialization period covers the remaining sample.*

**Panel A: Pre-Financialization (60 Day)**

Sector	Energy	Grains	Livestock	Metals	S&P500	Treasury	Tropical	Wood
Energy	100.00%							
Grains	7.24%	100.00%						
Livestock	11.35%	15.83%	100.00%					
Metals	13.53%	2.91%	-0.74%	100.00%				
S&P500	2.62%	-7.11%	7.51%	16.35%	100.00%			
Treasury	1.98%	-2.08%	1.93%	0.98%	25.00%	100.00%		
Tropical	9.35%	21.92%	8.02%	14.43%	-14.36%	-4.64%	100.00%	
Wood	-0.17%	-3.55%	7.39%	9.99%	-0.73%	8.46%	10.87%	100.00%

**Panel B: Pre-Financialization (90 Day)**

Sector	Energy	Grains	Livestock	Metals	S&P500	Treasury	Tropical	Wood
Energy	100.00%							
Grains	8.27%	100.00%						
Livestock	14.57%	27.49%	100.00%					
Metals	17.43%	0.96%	-11.63%	100.00%				
S&P500	-4.80%	-4.64%	8.83%	-10.32%	100.00%			
Treasury	4.61%	7.04%	5.95%	-10.41%	41.47%	100.00%		
Tropical	18.93%	33.66%	13.11%	16.39%	-15.46%	-12.94%	100.00%	
Wood	7.94%	4.20%	6.16%	-2.28%	-12.67%	11.30%	10.03%	100.00%

**Panel C: Financialization (60 Day)**

Sector	Energy	Grains	Livestock	Metals	S&P500	Treasury	Tropical	Wood
Energy	100.00%							
Grains	8.01%	100.00%						
Livestock	14.50%	9.58%	100.00%

Wood	33.87%	16.74%	13.97%	8.45%	26.04%	21.12%	12.25%	100.00%

**Table 9: Equity Risk Premia v.s. Commodity Variance Risk Premia: 60 Day**

*This table reports results of regressions of 60 day variance swap returns on the Fama–French 3 factors. Specifically, we run the following regression:*

$$LVRP_t = \alpha + \beta MKT_t + \gamma SMB_t + \delta HML_t + \epsilon$$

*where LVRP, MKT, and SMB denote the log variance risk premium, the market risk premium, small minus big, and high minus low factors, respectively. We download the Fama–French factors from French’s website. We report in brackets the Newey–West corrected t-statistics (with 1 lag) of the coefficient estimates.*

**Table 13: Price v.s. Variance Risk Premia**

*This table reports results of regressions of variance swap returns on commodity futures returns. Specifically, we run the following regression:*

$$LVRP_t = \alpha + \beta RET_t + \epsilon$$

*where LVRP and RET denote the variance swap and futures returns, respectively. We report in brackets the Newey–West corrected t-statistics (with 1 lag) of the coefficient estimates.*

**Table 14: Expected Variance Risk Premia**

*This table presents summary statistics of expected commodity variance risk premia. We use the historical variance of commodity returns as the floating leg of the variance swap. Columns entitled Mean, T-Stat, Median, AR(1), Min and Max report the average, Newey-West corrected t-statistic (same lag length as the maturity of the swap), median, first order auto-correlation, minimum and maximum variance risk premia, respectively. The next three columns display the standard deviation, skewness and kurtosis, respectively. The penultimate column reports the correlation between expected and realized variance risk premia. The last column shows the number of observations. Panel A presents the results for a horizon of 60 days, Panel B for a horizon of 90 days.*

**Table 16: Spline Interpolation: Variance Risk Premia**

*This table presents summary statistics of commodity variance risk premia. We use a cubic spline (rather than linear) interpolation to obtain a fine grid of implied volatilities. Columns entitled Mean, T-Stat, Median, AR(1), Min and Max report the average, Newey-West corrected t-statistic (same lag length as the maturity of the swap), median, first order auto-correlation, minimum and maximum variance risk premia, respectively. The next three columns report the standard deviation, skewness and kurtosis, respectively. "Corr" reports the correlation between the variance risk premia based on the cubic spline interpolation and those based on our (baseline) linear interpolation. The last column reports the number of observations. Panel A presents the results for a horizon of 60 days, Panel B for a horizon of 90 days.*

**Table 17: Spline Interpolation: Log Variance Risk Premia**

*This table presents summary statistics of commodity variance swap returns. We use a cubic spline (rather than linear) interpolation to obtain a fine grid of implied volatilities. Columns entitled Mean, T-Stat, Median, AR(1), Min and Max report the average, Newey-West corrected t-statistic (same lag length as the maturity of variance swaps), median, first order auto-correlation, minimum and maximum values of log variance risk premia, respectively. The next four columns report the standard deviation, skewness, kurtosis and Newey-West adjusted Sharpe Ratios (annualized), respectively. "Corr" reports the correlation between the log variance risk premia based on the cubic spline interpolation and those based on our (baseline) linear interpolation. The last column reports the number of observations. Panel A presents the results for a horizon of 60 days, Panel B for a horizon of 90 days.*

**Table 18: Truncation Points: Variance Risk Premia**

*This table presents summary statistics of commodity variance risk premia. We truncate the first and second integrals in Equation (3) at  $K_l$  and  $K_u$  as reflected by Equations ((12) and (13)). Columns entitled Mean, T-Stat, Median, AR(1), Min and Max report the average, Newey-West corrected t-statistic (same lag length as the maturity of the swap), median, first order auto-correlation, minimum and maximum variance risk premia, respectively. The next three columns display the standard deviation, skewness and kurtosis, respectively. "Corr" reports the correlation between the variance risk premia based on the tighter (8 standard deviations) truncation points and those based on our baseline truncation points (10 standard deviations). The last column presents the number of observations. Panel A presents the results for a horizon of 60 days, Panel B for a horizon of 90 days.*

**Table 19: Truncation Points: Log Variance Risk Premia**

*This table presents summary statistics of commodity variance swap returns. We truncate the first and second integrals in Equation (3) at  $K_l$  and  $K_u$  as reflected by Equations ((12) and (13)). Columns entitled Mean, T-Stat, Median, AR(1), Min and Max report the average, Newey-West corrected t-statistic (same lag length as the maturity of variance swaps), median, first order autocorrelation, minimum and maximum values of log variance risk premia, respectively. The next four columns report the standard deviation, skewness, kurtosis and Newey-West adjusted Sharpe Ratios (annualized), respectively. "Corr" reports the correlation between the log variance risk premia based on the tighter (8 standard deviations) truncation points and those based on our baseline truncation points (10 standard deviations). The last column presents the number of observations. Panel A presents the results for a horizon of 60 days, Panel B for a horizon of 90 days.*

**Table 20: The Role of Jumps: Variance Risk Premia**

*This table presents summary statistics of commodity variance risk premia. We account for the role of jumps in the variance swap rate by using the approach of Rompolis and Tzavalis (2013). Columns entitled Mean, T-Stat, Median, AR(1), Min and Max report the average, Newey-West corrected t-statistic (same lag length as the maturity of the swap), median, first order auto-correlation, minimum and maximum variance risk premia, respectively. The last four columns display the standard deviation, skewness, kurtosis and number of observations, respectively. Panel A presents the results for a horizon of 60 days, Panel B for a horizon of 90 days.*

**Panel A: 60 Day Variance risk premia**

**Table 22: The Role of Transaction Costs: VRP**

*This table presents summary statistics of commodity variance risk premia after accounting for transaction costs. We use two distinct approaches to capture transaction costs. "Proportional" assumes that the true variance swap rate is 95% of the synthetic variance swap rate. For example, if the synthetic variance swap rate is 10%, the true variance swap rate is 9.5%. "Fixed" assumes that the square root of the true variance swap rate is 1% less than the square root of the synthetic variance swap rate. For example, if the square root of the synthetic variance swap rate is 10%, then the square root of the true variance swap rate is 9%. Columns entitled Mean and T-Stat report the average and Newey-West corrected t-statistic (same lag length as the maturity of the swap), respectively. Nobs shows the number of observations. Panel A presents the results for a horizon of 60 days, Panel B for a horizon of 90 days.*

**Panel A: 60 Day Variance risk premia**

**Table 24: Seasonality and Comovements in Variance Swap Returns**

*This table summarizes the correlations of deseasonalized log variance risk premia within and across commodity sectors. In Panel A, we report the average pair-wise correlation across all commodities of the same family. For example, we calculate the pair-wise correlations between crude oil, heating oil and natural gas. We then compute the average of these correlations which we report under the appropriate sector: energy. Columns headed “60-Day” and “90-Day” indicate a maturity of 60 and 90 days, respectively. Panels B and C report correlations across different commodity sectors for variance swaps of maturity 60 and 90 days, respectively. These correlations are calculated as follows. For each sector and trading day, we calculate the return on an equally-weighted portfolio of variance swaps of all commodities belonging to that specific sector. After calculating the returns of each portfolio, we compute the pair-wise correlations of returns across sectors, which we report in Panels B and C.*

**Panel A: Commonalities Within Sector**

Sector	Correlation	
	60 Day	90 Day
Energy	33.35%	32.82%
Grains	24.03%	20.32%
Livestock	33.08%	25.12%
Metals	30.18%	34.11%
Tropical	3.54%	7.47%
Wood	—	—

**Panel B: Commonalities Across Sectors (60 Day)**

Sector	Energy	Grains	Livestock	Metals	S&P500	Treasury	Tropical	Wood
Energy	100.00%							
Grains	10.50%	100.00%						
Livestock	16.56%	17.36%	100.00%					
Metals	21.84%	10.81%	15.08%	100.00%

S&P500	27.40%	2.87%	10.78%	32.26%	100.00%			
Treasury	23.49%	22.50%	12.98%	9.06%	51.89%	100.00%		
Tropical	14.90%	32.91%	12.66%	11.79%	-2.53%	-4.19%	100.00%	
Wood	17.81%	4.79%	14.21%	-2.94%	6.37%	17.31%	8.05%	100.00%

**Table 25: Non-Overlapping Variance Risk Premia**

*This table displays summary statistics for non-overlapping variance risk premia. Mean, T-Stat, Median, AR(1), Min and Max report the average, Newey-West corrected t-statistics (6 lags), median, first order auto-correlation, minimum and maximum values, respectively. Std Dev, Skew and Kurt refer to standard deviation, skewness and kurtosis. The last column reports the number of observations.*
